Can Cosmic Parallax Distinguish Between Anisotrophic Cosmologies?

Abstract
In an anisotropic universe, observers not positioned at a point of special symmetry should observe cosmic parallax—the relative angular motion of test galaxies over cosmic time. It was recently argued that the nonobservance of this effect in upcoming precision astrometry missions such as GAIA may be used to place strong bounds on the position of off-center observers in a void-model universe described by the Lemaitre-Tolman-Bondi metric. We consider the analogous effect in anisotropic cosmological models described by an axisymmetric homogeneous Bianchi type I metric and discuss whether any observation of cosmic parallax would distinguish between different anisotropic evolutions.

I. INTRODUCTION

Homogeneity and isotropy are the cornerstones of the standard cosmological model, providing not only a tremendous simplification of general relativity, but remarkable agreement with all observations. Homogeneity is supported by the observed galaxy distribution from large-scale structure surveys, while isotropy is supported by, in particular, the remarkable uniformity of the average temperature of the cosmic microwave background radiation (CMB). Nevertheless, the paradigm-changing observation of cosmic acceleration, now more than a decade old, has forced cosmologists to reexamine even their most cherished assumptions, including the correctness of general relativity, a vanishing cosmological constant, and, more recently, homogeneity and isotropy.

The primary evidence for the accelerating universe comes from the unexpected dimming of type Ia supernovae [1–8], as measured through their light curves. The connection to cosmic acceleration requires the assumptions of homogeneity and isotropy, and thus this raises the possibility that abandoning one of these principles may allow for the appearance of accelerated expansion without actual acceleration itself.

Of course, the usual cosmological Friedmann-Robertson-Walker (FRW) metric is so simple by virtue of its underlying symmetries. Abandoning these leads to a correspondingly more complicated metric. It is convenient therefore to begin by studying toy models. One class of these that has shown some promise in this direction are the Lemaitre-Tolman-Bondi (LTB) metrics, in which we are assumed to live inside a spherically symmetric underdense region of spacetime (or “void”) embedded in an otherwise spatially flat and homogeneous Einstein-de Sitter universe [9–15]. Such a spacetime is manifestly inhomogeneous, due to the void, and on its own violates any strong version of the Copernican principle, since we must live inside this void in order to account for the observed supernovae dimming. Nevertheless, it has been shown that these models can provide a satisfactory fit to the luminosity distance-redshift relation of type Ia supernovae and the position of the first peak in the CMB [15,16]. Thus, LTB models have been suggested as a possible solution to the problem of cosmic acceleration, obviating the need for quintessence fields, modifications of gravity, or a cosmological constant, and considerable effort has been devoted to constraining them [17–21].

Beyond the usual cosmological tests of homogeneity and isotropy, it has recently been suggested that these models could be further constrained by real time cosmological measurements—in particular, precision measurements of the evolution of the angular positions of distant sources. Following the authors of [22], we refer to this effect as cosmic parallax. The expansion of an FRW universe is isotropic for all observers, and so cosmic parallax would not be observed. Of course although our universe is very close to an FRW universe, it is not exactly so—for example, on large scales bound structures may acquire small peculiar velocities, giving rise to a slight deviation from observed isotropic expansion. However, to any observer living off-center inside the void of an LTB universe, cosmic evolution itself is anisotropic and is an additional source of cosmic parallax. For sufficiently off-center observers the cosmic parallax due to anisotropic expansion would dominate over the contribution from peculiar velocities. Cosmic parallax could therefore provide an interesting test of void models. Upcoming sky surveys such as GAIA [23] may be able to initiate a measurement of this effect, requiring only that a similar survey be completed 10 years later in order to complete the measurement. The absence of cosmic parallax beyond what is expected from peculiar velocities would put an upper bound on how far our galaxy could be from the center of the void in otherwise allowed LTB models. For example, the au-

† ejwest@physics.syr.edu
‡ trodden@physics.upenn.edu
Here and throughout the rest of the paper, unless otherwise indicated, by cosmic parallax we mean cosmic parallax due to anisotropic expansion about an observer. The LTB metric is given by \[ ds^2 = -dt^2 + \frac{|R(t, r)|^2}{1 + \beta(r)} dr^2 + R^2(t, r)d\Omega^2, \] (1)

where \( R(t, r) \) is a position-dependent scale factor, \( \beta(r) \) is related to the curvature of the spatial slices, and \( d\Omega \) is the solid angle. The Einstein equations relate \( R(t, r) \) to \( \beta(r) \) and an additional arbitrary function of integration \( \alpha(r) \). Specifying \( \alpha(r) \), \( \beta(r) \), and an initial condition for \( R(t, r) \) completely determines the spacetime. In models with an underdense region, or void, surrounded by an overdense region, \( \alpha(r) \) and \( \beta(r) \) roughly correspond to the width of the void and the gradient of the boundary between the inner and outer regions, respectively, and will be specified below.

The LTB metric describes a region of spacetime that is isotropic about the origin but inhomogeneous with respect to the radial direction. Therefore distant galaxies appear to be receding at the same rate in all directions for observers located at the origin. On the other hand, observers located away from the center of the void could in principle observe anisotropic recession. One way to observe this effect [22] is to measure how the angle between the positions of two distant sources evolves over time. This difference is referred to as the cosmic parallax. To study this, one considers null geodesics in an LTB universe, obeying

\[ \frac{d^2x^\mu}{d\lambda^2} + \Gamma^\mu_{\rho\sigma} \frac{dx^\rho}{d\lambda} \frac{dx^\sigma}{d\lambda} = 0. \] (2)

Here \( \Gamma^\mu_{\rho\sigma} \) are the Christoffel symbols, \( \lambda \) is an affine parameter along null geodesics, and the four-velocities \( u^\mu \equiv \frac{dx^\mu}{d\lambda} \) satisfy \( u^\mu u_\mu = 0 \). The goal will be to solve these equations to determine the null geodesics along which light travels from various sources to an observer, and to do this for two different observation times.

Following [22], we work in spherical-polar coordinates \((t, r, \theta, \phi)\) for which the origin coincides with the center of the void (labeled "O" in Fig. 1).

Without loss of generality we choose the observer to lie on the polar axis at a coordinate distance \( r_0 \) along it. Spherical symmetry about the observer is now broken but the remaining cylindrical symmetry applied to (2) allows us to neglect the polar angle \( \phi \) dependence. The system then reduces to three second-order geodesic equations, or equivalently six first-order equations. Applying the null geodesic condition further reduces the system to five independent first-order equations for \( t, r, \theta, p \equiv \frac{dr}{d\lambda} \) and the redshift \( z \) as [17,22]

\[ \frac{dt}{d\lambda} = -\sqrt{\frac{(R^2)^2}{1 + \beta} - \frac{j^2}{R^2}} \] (3)

\[ \frac{dr}{d\lambda} = p \] (4)

\[ \frac{d\theta}{d\lambda} = 0 \] (5)

\[ \frac{d\phi}{d\lambda} = 0 \] (6)

\[ \frac{d\lambda}{d\lambda} = 1 \] (7)

\[ \frac{dR}{d\lambda} = 0 \] (8)
CAN COSMIC PARALLAX DISTINGUISH BETWEEN . . .

This expression can be used to express $J_0$ and $p_0$ in terms of $t_0$, $r_0$, and $\xi_0$, via

$$J_0 = R(t_0, r_0) \sin \xi_0 \quad p_0 = \frac{\cos \xi_0}{R'(t_0, r_0)} \sqrt{1 + \beta(r_0)}. \quad (9)$$

Therefore, the system is completely determined by specifying $t_0$, $r_0$, $\theta_0$, $\zeta_0$, and $\xi_0$.

Clearly, our coordinate choice means that $\theta_0 = 0$, and our conventional definition of redshift yields $\zeta_0 = 0$. Following [22] we choose $r_0 = 15$ Mpc, which is the largest value consistent with the CMB dipole [17]. What remains is to specify a direction on the sky and the time of observation to uniquely determine a geodesic that terminates at the spacetime event of observation. This picks out an initial geodesic along which light from a distant source travels to reach the observer.

Given the redshift and line of sight angle of a source at an initial time, we can determine the trajectory of light from that source at a later time in the following way. As just mentioned, the line of sight angle $\xi_0$ picks out an initial geodesic, terminating at the initial observation event. The observed redshift determines how far backwards in time along this initial geodesic the source lies. We extract the comoving coordinates of the source by numerically integrating backwards along this initial geodesic. Once the comoving coordinates of the observer and source are determined, and the interval of time between observations is specified, we solve a boundary-value problem to determine the final geodesic. We then extract the line of sight angle of this final geodesic $\xi_f$.

After repeating this procedure for two sources we have four angles: the input angles $\xi_{a0}$ and $\xi_{b0}$ and the output angles $\xi_{af}$ and $\xi_{bf}$. We may then compute the difference

$$\Delta \gamma = \gamma_f - \gamma_0 = (\xi_{af} - \xi_{bf}) - (\xi_{a0} - \xi_{b0}), \quad (10)$$

which is the main quantity of interest, hereafter referred to as the cosmic parallax.

In [22] this quantity is calculated for LTB models characterized by the functions

$$\beta(r) = (H_0^{\text{OUT}})^2 r^3 - r \beta(r), \quad (11)$$

which characterize the smooth transition from the inner underdense region to the outer, higher density region. The quantities $\Delta \alpha$, $r_{vo}$, $\Delta r$, and $H_0^{\text{OUT}}$ are free parameters of the model that can be tuned to fit CMB and supernovae measurements. Following [15,22], we choose a model which is in good agreement with SNIa observations and the location of the first peak of the CMB, namely $\Delta \alpha = 0.9$, $r_{vo} = 1.3$ Gpc, $\Delta r = 0.4 r_{vo}$, and $H_0^{\text{OUT}} = 51$ kms$^{-1}$Mpc$^{-1}$. Although this Hubble parameter outside the void seems to be in conflict with the measured Hubble Key project value of $72 \pm 8$ kms$^{-1}$Mpc$^{-1}$ [38], one should keep in mind that the measurements made to determine this value

FIG. 1. In the LTB model the observer is located at a distance $r_0$ from the center of the void along the axis of symmetry. Each point along the geodesic is described by the spatial coordinates $(\theta(\lambda), r(\lambda))$ or equivalently by $x'(\lambda)$.
are spatially homogeneous \cite{40,41}. In particular, we focus on parallax in alternative anisotropic cosmologies and universe. To understand this, we study cosmic anisotropies that would not itself be evidence that we live in an LTB universe around a given observer contributes to cosmic parallax, since such an observation would not serve as useful toy models to study the characteristics and magnitude of the parallax signal.

The authors of \cite{22} numerically compute the cosmic parallax for two different models. They find an angle-dependent signal with maximal value roughly 0.18 $\mu$ as for sources at redshift of 1. It is claimed that this signal is within reach of the forthcoming Gaia mission, provided Gaia produces a sky map of the expected number of quasars (roughly 500,000) with final positional error less than 30 $\mu$as, and that such measurements are repeated after 10 years.

III. BIANCHI TYPE I MODELS

As we have discussed, anisotropic expansion of the universe around a given observer contributes to cosmic parallax. In the case of LTB models, this may allow us to constrain the distance of our galaxy from the center of the void. The further we are from the center of the void, the more anisotropic the universe would look to us. Of course, LTB spacetimes are not the only ones that can give rise to anisotropic expansion around a point. This raises the question of how we might interpret any observation of an anomalously large cosmic parallax, since such an observation would not itself be evidence that we live in an LTB universe. To understand this, we study cosmic parallax in alternative anisotropic cosmologies and compare our results with those obtained in \cite{22}.

For simplicity we consider anisotropic spacetimes that are spatially homogeneous \cite{40,41}. In particular, we focus on a subclass of Bianchi Type I spacetimes, the metric for which may be written as

$$ds^2 = -dt^2 + a_1^2(t)dx^2 + a_2^2(t)dy^2 + a_3^2(t)dz^2.$$  \hspace{1cm} (13)

In general, $a_1(t)$, $a_2(t)$, and $a_3(t)$ are independent scale factors, describing how the spatial directions scale with time, which reduces to the standard FRW case when $a_1(t) = a_2(t) = a_3(t)$. We specialize to the case when only one of the scale factors differs from the others, say $a_1(t) = a_2(t) \neq a_3(t)$, in which case the expansion is axisymmetric. We do so because we want to compare our results to observations made by an off-center observer in an LTB void. Such an observer will experience axisymmetric cosmic expansion, and so the most direct comparison will be to an axisymmetric Bianchi-I universe. There is, however, an important difference in the symmetries around observ-

ers in these two spacetimes. In the axisymmetric Bianchi-I universe there is an additional plane of symmetry normal to the axis of symmetry. The same is not true for an off-center observer in an LTB universe. To see this, it is sufficient to consider the extremal case of an observer outside the void, who can obviously distinguish the two directions along the polar axis: toward the void and away from it. This suggests that cosmic parallax in these two types of anisotropic models will differ at least qualitatively, if not in magnitude.

Setting $a_1 = a_2 = a(t)$ and $a_3 = b(t)$ in (13), the Einstein equations become

$$H_a^2 + 2H_aH_b = 8\pi G\rho$$  \hspace{1cm} (14)

$$2\dot{H}_a + 3H_a^2 = -8\pi GP_z$$  \hspace{1cm} (15)

$$\dot{H}_a + H_a^2 + \dot{H}_b + H_a^2 + H_aH_b = -8\pi GP_z,$$  \hspace{1cm} (16)

where an overdot denotes a derivative with respect to $t$, $P_\chi = P_\chi$, and $P_z$ are anisotropic pressures in the different directions, and we have defined the Hubble parameters $H_a = \dot{a}/a$ and $H_b = b/b$. The conservation of energy equation in this case is

$$\dot{\rho} = -2H_a(\rho + P_\chi) - H_b(\rho + P_z).$$  \hspace{1cm} (17)

The observational success of FRW cosmology places tight constraints on how anisotropic the universe can be. In order to restrict ourselves to solutions that remain close to an FRW cosmology, we split each of these exact equations into an FRW part which evolves according the FRW equations of motion, and a non-FRW part which we require to remain small, in a sense that we will now make clear. A similar approach was used in \cite{42}. We define

$$H_a(t) = \tilde{H}(t) + \epsilon f(t)$$  \hspace{1cm} (18)

$$H_b(t) = \tilde{H}(t) + \epsilon g(t)$$  \hspace{1cm} (19)

$$\rho(t) = \tilde{\rho}(t) + \epsilon \rho(t)$$  \hspace{1cm} (20)

$$P_\chi(t) = P_\chi(t) = \tilde{P}(t)$$  \hspace{1cm} (21)

$$P_z(t) = \tilde{P}(t) + \epsilon s(t)$$  \hspace{1cm} (22)

where overbars denote the FRW quantities and $\epsilon$ is a small perturbative parameter for which we will determine an upper bound later. Substituting these definitions into Eqs. (14)–(17) and collecting powers of $\epsilon$ gives the zeroth-order (or background) equations, which are just the usual ones of the FRW metric, and the first-order equations

$$2\tilde{H}(f + 2g) = 8\pi G\rho$$  \hspace{1cm} (23)

$$6\tilde{H}f + 2\tilde{f} = -8\pi Gs$$  \hspace{1cm} (24)
where the parameter $\sigma$ is taken to be constant. Note that this is analogous to $\dot{P} = w\dot{\rho}$, except that it relates the anisotropic component of the pressure to the non-FRW correction of the energy density. The value of $\sigma$ will be important in determining whether the non-FRW parts of Eqs. (23)–(26) grow or decay in time.

Realistic models will be those for which the amount of anisotropy is sufficiently small in the past and present. Assuming the anisotropy is set (for example by inflation) to be sufficiently small at some early epoch, the question then is whether the anisotropy grows or not. In our setup this corresponds to asking whether the non-FRW parts of Eqs. (23)–(26) grow or not, and if so, how quickly. We will see that $\sigma$ governs the general behavior of the non-FRW quantities, but for a given $\sigma$, the details will depend on the background (FRW) solution. Since we are integrating from the present up to redshifts of order 1, our background is well described by the $\Lambda$CDM model. Using this background we can analytically find the asymptotic behavior of the non-FRW quantities for different values of the equation state parameter $\sigma$.

The background energy density and pressure for $\Lambda$CDM are

$$\dot{\rho} = \ddot{\rho}_m + \rho_\Lambda \quad \ddot{P} = -\rho_\Lambda,$$

where $\rho_m$ is the background energy density of matter and $\rho_\Lambda$ is the effective energy density of the cosmological constant. The background equations become

$$3H^2 = 8\pi G(\rho_\Lambda + \rho_m)$$

$$2\dot{H} + 3H^2 = 8\pi G\rho_\Lambda$$

$$\dot{\rho}_m = -3H\dot{\rho}_m.$$  

The solutions can be written simply

$$\dot{H}(t) = A\coth\left(\frac{3}{2}At\right)$$

$$\dot{\rho}_m = \rho_\Lambda\left(\sinh\left(\frac{3}{2}At\right)\right)^2$$

$$A = \sqrt{\frac{8\pi G\rho_\Lambda}{3}}.$$  

Using (23) and (27) in (26) then gives

$$\dot{r} = -\left[(3 + \sigma)A\coth\left(\frac{3}{2}At\right) + \frac{12A\pi G}{\sinh^2\left(\frac{3}{2}At\right)}\right]r(t),$$

which can be integrated to find

$$r(t) = c_1\cosh\left(\frac{3}{2}At\right)\left[\sinh\left(\frac{3}{2}At\right)\right]^{-\left(3 + (2/3)\sigma\right)}.$$  

Using the equation of state (27) immediately gives $s(t)$. Eqs. (24) and (25) can then be integrated to find the remaining solutions (for $\sigma \neq -9/2$)

$$f(t) = \frac{A}{\cosh^2\left(\frac{3}{2}At\right)}\left(c_2 + \frac{3c_1}{2}\left[\cosh\left(\frac{3}{2}At\right)\right]^{2/3}\right)$$

$$g(t) = -f(t) - \frac{Ac_2}{\cosh^2\left(\frac{3}{2}At\right)}.$$  

Now we consider the asymptotic behavior of these solutions for $t \to \infty$ and $t \to 0$ in turn.

The behavior as $t \to \infty$ is

$$r(t) \sim s(t) \sim c_1\left[\sinh\left(\frac{3}{2}At\right)\right]^{-\left(2 + (1/3)\sigma\right)}.$$  

$$f(t) \sim -g(t) \sim c_1\left[\sinh\left(\frac{3}{2}At\right)\right]^{\left[\max\left[-2, -2 + (1/3)\sigma\right]\right]}.$$  

Here we see that $\sigma = -3$ is the boundary between growing and decaying solutions. If we require all of the non-FRW quantities to decay as $t \to \infty$, then we must restrict ourselves to $\sigma > -3$.

As $t \to 0$, the situation is slightly more complicated. The behavior of $f(t)$ and $g(t)$ have a part that depends on the value of $\sigma$ and a part that does not. The part that does not behaves as

$$c_2\left[\frac{A}{\cosh^2\left(\frac{3}{2}At\right)}\right]^2 \sim c_2t^{-2}, \quad t \to 0,$$

whereas the part that depends on $\sigma$ behaves as

$$\frac{c_1}{2}\left[\frac{A}{\cosh^2\left(\frac{3}{2}At\right)}\right]^{\left[1 + (1/3)\sigma\right]} \sim c_1t^{-2\left[1 + (1/3)\sigma\right]}, \quad t \to 0.$$  

We require that the expansion history is close to FRW in the far past, which amounts to demanding that $|f/H|$, $|g/H|$, etc. remain $\leq O(1)$ as $t \to 0$. From the first term, this requires that $c_2 = 0$, while the second term requires that $\sigma < -3/2$. Therefore solutions with decaying anisotropy have an equation of state parameter lying in the range $-3 < \sigma < -3/2$. Turning to $r(t)$ and $s(t)$, as $t \to 0$ we have

$$r(t) \sim s(t) \sim c_1\left[\sinh\left(\frac{3}{2}At\right)\right]^{-\left(3 + (2/3)\sigma\right)}.$$  

When $\sigma > -3$ these solutions diverge as $t \to 0$, but if $\sigma < -3/2$ they diverge slower than $\dot{\rho}$ and $\ddot{P}$, respectively. So
the condition

$$-3 < \sigma < -\frac{3}{2}$$

(41)

will ensure that all non-FRW quantities remain small in the far past, as required. We will restrict ourselves to these models in the rest of the paper.

What remains is to fix $c_1$ and the constant $A$ in the solutions (35)–(37). We do this by imposing observational constraints on the models of interest. First we impose a condition at the surface of last scattering. For an anisotropically expanding universe to be viable it must at the very least predict angular variations in the temperature of the CMB no bigger than $10^{-5}$. We can estimate the maximum temperature difference at the time of last scattering by

$$\Delta T_0 = |T_0^{xy} - T_0^{zz}| = \left| T_{\text{ls}}\left(\frac{a_{\text{ls}}}{a_0}\right) - T_{\text{ls}}\left(\frac{b_{\text{ls}}}{b_0}\right) \right|.$$  

(42)

where $T^x$ is the temperature along the axis of symmetry and $T^{xy}$ is the temperature in the transverse plane; subscripts “0” and “ls” refer to quantities today and at the last scattering surface, respectively. Recall that $b(t)$ is the scale factor along the axis of symmetry and $a(t)$ is the scale factor in the transverse plane. From the definitions of $H_a$ and $H_b$, we have

$$a(t) = a_0 \exp\int_{t_0}^t (\dot{H}(t') + \epsilon f(t'))dt',$$

(43)

$$b(t) = b_0 \exp\int_{t_0}^t (\dot{H}(t') + \epsilon g(t'))dt'.$$

(44)

Using these, and choosing $a_0 = b_0 = 1$, we can rewrite the expression for $\Delta T_0$ to first order in $\epsilon$ as

$$\Delta T_0 = T_{\text{ls}}\left(\frac{b_{\text{ls}}}{b_0}\right) |1 - (\frac{a_{\text{ls}}}{b_{\text{ls}}}(\frac{b_0}{a_0})| \approx 2\epsilon T_0^3 \left| \int_{t_0}^{t_{\text{ls}}} f(t) dt \right|.$$  

(45)

where we have used the fact that $g(t) = -f(t)$, which is a consequence of requiring $c_2 = 0$. Inserting the solution for $f(t)$ gives

$$\frac{\Delta T_0}{T_0^3} \approx 3A \epsilon c_1 \int_{t_0}^{t_{\text{ls}}} \left[ \sinh\left(\frac{3}{2}At\right) \right]^{-2(1+(\sigma/3))} dt.$$  

(46)

Demanding the left-hand side to be at most $1.3 \times 10^{-6}$ [43] yields one condition on the product $\epsilon c_1$ and $A$ for a given equation of state parameter $\sigma$.

In order to break the degeneracy between $\epsilon c_1$ and $A$, we need one further condition. Equation (46) already requires the difference between $H_a$ and $H_b$ to be small—well within the accepted uncertainty in the measured value of the Hubble parameter [39]. We find it convenient to choose to set the arithmetic average of the Hubble parameters in the three directions equal to the observed value.

$$H_{\text{obs}} = \frac{2H_a + H_b}{3} = \bar{H} + \frac{\epsilon}{3} f(t),$$

(47)

where again we have used the fact that when $c_2 = 0$, $g(t) = -f(t)$. Alternative choices, such as setting $H_a$ or $H_b$ equal to the measured value of the Hubble parameter, would not change the order of magnitude of $\epsilon c_1$ and $A$ and would leave the final result essentially unaltered. Inserting the solution for $f(t)$ into Eq. (47) gives a second condition on $\epsilon c_1$ and $A$

$$\epsilon c_1 = \frac{2}{A} (H_{\text{obs}} - \bar{H}) \left[ \sinh\left(\frac{3}{2}At\right) \right]^{2(1+(\sigma/3))}. $$

(48)

We can (numerically) solve this equation for $A$ in terms of $\epsilon c_1$ and then substitute it back into the first condition (46) to obtain an upper bound on $\epsilon c_1$. By taking the maximal allowed value for $\epsilon c_1$, we can then find $A$ using (48). For $\sigma = -2$ we find $A \approx 62$ (km/s)/Mpc and $\epsilon c_1 \approx 1.3 \times 10^{-6}$. We always take $c_1$ to be $O(1)$, and so in this case we choose $c_1 = 1.3$ and $\epsilon = 10^{-6}$.

In this way we can fully determine solutions to the non-FRW quantities for a given equation of state parameter $\sigma$. By restricting ourselves to $-3 < \sigma < -3/2$ we have chosen to focus on models for which these solutions decay in the distant future and which diverge slower than the respective background quantities in the far past as one approaches the initial singularity. These models seem to be the most conservative realizations of a Bianchi-I cosmology, in the sense that they are the easiest to make consistent with observations, or alternatively, the most difficult to rule out. One might try to push the boundaries slightly, for example, by considering models with anisotropies that approach a constant in the distant future rather than vanishing. It may be that such models can be carefully tuned to match observations. We do not consider these more general models here, since our main interest is not model-building, but rather to explore a general effect (cosmic parallax) arising in a Bianchi-I universe.

**IV. GEODESICS AND COSMIC PARALLAX IN AXISYMMETRIC BIANCHI-I MODELS**

As in Sec. II, in order to analyze cosmic parallax we need to find null geodesics in the spacetime that connect an observer and various sources at two different times. Letting Latin indices run over 1, 2, 3 and $(x^0, x^1, x^2, x^3) = (t, x, y, z)$, the nonzero Christoffel symbol components for the Bianchi-I metric in (13) are

$$\Gamma^0_{ij} = a_i^2 H_i \delta_{ij}, \quad \Gamma^i_{0j} = H_i \delta^i_j,$$

where no sum on the index $i$ is implied and $H_i$ is defined as above. The four geodesic equations are then

$$\frac{d^2x^i}{d\lambda^2} = -\sum_i H_i \left( \frac{dx^i}{d\lambda} \right)^2.$$  

(49)
\[
\frac{d^2x^i}{d\lambda^2} = -2H \frac{dt}{d\lambda} \frac{dx^i}{d\lambda},
\]  
\tag{50}
\]

with the null geodesic condition, \(u^\mu u_{\mu} = 0\), becoming
\[
\left(\frac{dt}{d\lambda}\right)^2 = \sum_i \left(\frac{u^i}{a(t)} \frac{dx^i}{d\lambda}\right)^2. \tag{51}
\]

As before, \(u^\mu = dx^\mu/d\lambda\). We specialize to the axisymmetric case by setting \(a_1 = a_2 = a(t)\) and \(a_3 = b(t)\), and also \(H_1 = H_2 = H_a\) and \(H_3 = H_b\). The scale factors, \(a(t)\) and \(b(t)\), and Hubble parameters, \(H_a(t)\) and \(H_b(t)\), are fixed after choosing \(\sigma\) and solving the full set of equations as in the previous section.

After fixing the background Bianchi-I spacetime, Eqs. (49) and (50) yield four second-order differential equations and one constraint equation in four dependent variables. To solve this system we must in principle specify initial conditions for the four dependent variables as well as initial velocities (derivatives with respect to \(\lambda\)) giving a total of eight conditions. However, using the constraint equation the system can be reduced to seven independent first-order equations.

Considering the \(u^\mu(t) = dx^\mu(t)/d\lambda\) as functions of time along the geodesic, Eqs. (50) can be integrated immediately to give
\[
u'(t) = u_0' e^{-2 \int_{t_0}^{t} H_i(t')dt'} = u_0' a_i^{-2}(t), \tag{52}
\]
which can then be used in Eq. (51) to give
\[
\left(\frac{dt}{d\lambda}\right)^2 = \sum_i \left(\frac{u_0^i}{a(t)}\right)^2. \tag{53}
\]

As in the LTB case it is again useful to find an expression for the redshift as it will be one of our observational inputs. To find this expression, as usual, we consider two photons emitted from a source at times \(t\) and \(t + \tau\), respectively, where \(\tau\) is taken to be infinitesimally small. The trajectory of the first photon is described by Eq. (53), while to first order in \(\tau\), the trajectory of the second photon is described by the geodesic equation
\[
\left(\frac{dt}{d\lambda}\right)^2 + 2 \frac{dt}{d\lambda} \frac{d\tau}{d\lambda} = \sum_i (u^i a_i)^2 (1 + 2 \tau H_i). \tag{54}
\]

Here the variation in time corresponds to a time-delay, and so to a change in geodesic, and not to a change of the time coordinate along a fixed geodesic. Since the \(u'(\lambda)\) are directional derivatives along a given geodesic, they remain unaffected by time variations (derivatives) in obtaining this equation. Using the standard definition of redshift, \(1 + z(\lambda_{em}) = \tau(\lambda_{ob})/\tau(\lambda_{em})\), we find the relation
\[
\frac{d\log(1 + z(\lambda_{em}))}{d\lambda_{em}} = -\frac{1}{\tau(\lambda_{em})} \frac{d\tau(\lambda_{em})}{d\lambda_{em}}, \tag{55}
\]
where \(\lambda_{em}\) and \(\lambda_{ob}\) are the values of the affine parameter at the emission and observation event, respectively. Using this in (54) gives
\[
\frac{d\log(1 + z)}{d\lambda} = -\frac{\sum_i (u^i a_i)^2 H_i}{\sqrt{\sum_i (u^i a_i)^2}} = \frac{d\log\left(\sum_i (u^i a_i)^2\right)}{d\lambda}. \tag{56}
\]

In the last step we have also made use of (52) and the chain rule
\[
\frac{d}{d\lambda} (u^i a_i(\lambda)) = -\frac{dt}{d\lambda} (a_i(t) u_i H_i(t)).
\]

With the initial condition \(z(\lambda_0) = 0\), integrating (56) then gives
\[
(1 + z) = \frac{\sqrt{\sum_i (u^i a_i)^2}}{\sqrt{\sum_i (u_0^i a_i)^2}}. \tag{57}
\]

As in Sec. II, we would like to express our results not only in terms of redshift but also in terms of angles, since these are the actual observables. In general there are four pieces of data for each object in the sky, namely, the time of observation, two angles with respect to an arbitrary coordinate system, and the observed redshift of the source. In the case of cylindrical symmetry one angle is enough. In contrast with LTB spacetimes, not much is gained in this case by rewriting the geodesic equations in terms of angles and redshift. Instead, we numerically integrate the equations in the above coordinates and then express the results in terms of angles and redshift.

Our procedure for computing the cosmic parallax for these models is analogous to that in Sec. II. We work in local Cartesian coordinates \((t, x_1, x_2, x_3)\) in which the observer is located at the origin. As seen above, the system of four second-order differential equations plus a constraint reduces to seven independent first-order equations, some of which can be integrated immediately by hand. We are then left with the problem of fixing initial conditions for our complete set of equations
\[
\frac{dt}{d\lambda} = -\sqrt{\sum_i (u^i a_i)^2}\tag{58}
\]
\[
u'(\lambda) = \frac{u_0'}{a_0'}\tag{59}
\]
\[
\frac{dx^i}{d\lambda} = u^i,\tag{60}
\]
where the subscripts \(0\) refer to quantities at the initial observation event, corresponding to \(\lambda = 0\). To close the system requires seven initial conditions that unfortunately cannot be all specified at the observation event. By construction we have \(x'_0 = 0\), leaving four remaining conditions, three of which are obtained by specifying \(t_0\) and two
initial spatial velocities in terms of measurable quantities (angles), while the last one is given by the observed redshift. We integrate backwards along the initial geodesic until reaching the desired redshift and then find the comoving coordinates of the source. To find the final geodesic that connects the same source with the observer at a later time \( t_0 + \Delta t \), we solve the corresponding boundary-value problem (namely, to find solutions of the null geodesic equations with two fixed endpoints). We then find the velocities along the final geodesics at the time of observation.

This procedure is repeated for two sources, yielding four sets of velocities: one set for each initial geodesic and one set for each final geodesic. The velocities \( u^i \) and \( v^i \) along two geodesics at the same observing time (see Fig. 2) are related to the angle \( \gamma \) between them by

\[
\cos(\gamma) = \frac{\sum a_i^2 u^i v^i}{\sqrt{\left(\sum (a_i u^i)^2\right)\left(\sum (a_i v^i)^2\right)}}.
\]  

We then calculate the cosmic parallax \( \Delta \gamma \), as defined in (10), by taking the difference of the angle between the two sources at the two different times. Finally, we plot the cosmic parallax as a function of the polar coordinate \( \theta \) for one of the sources. By convention we choose the second, or trailing, source as our reference, as shown in Fig. 3. We find the parallax for two hypothetical sources with the same redshift, initially separated by a given angle on the sky, and for a given \( \Delta t \) and \( \epsilon \). In Fig. 4 we plot the parallax for two hypothetical sources at \( z = 1 \), with an initial separation of 90 degrees on the sky, for \( \epsilon = 10^{-6} \) and various values of \( \Delta t \). For \( \Delta t = 500 \) years and \( \epsilon = 10^{-6} \) we find this maximal value to be of the order of \( 6 \times 10^{-14} \) radians. Of course, our true goal is to find the maximal signal for reasonable time scales, say \( \Delta t \sim 10 \) years, but unfortunately numerical noise dominates over the signal for \( \Delta t \) of that magnitude. One can see from the first quadrant of Fig. 4 that by \( \Delta t = 20 \) years the signal-to-noise ratio becomes very poor, making it difficult to extract trustworthy predictions. Therefore, although we can directly compute the signal for this model at \( \Delta t = 10 \) years, we prefer to calculate the cosmic parallax for several values of \( \Delta t \) between 5 and 500 years and interpolate the value at 10 years. Since our primary goal is to find an order of magnitude estimate for the effect, this approach should be acceptable. Figure 5 shows the values of the cosmic parallax between two sources for decreasing values of \( \Delta t \) for a specific direction \( \theta \) in the sky (keeping all other values fixed). For each value of \( \theta \), we use a linear fit passing through the origin (because cosmic parallax must vanish for \( \Delta t = 0 \)) to find the interpolated value at 10 years. We could just as well perform an extrapolation by omitting data below some cutoff, say \( \Delta t = 50 \) years. This does not have any noticeable effects on our results.

To check the consistency of this procedure we repeat the same analysis, except now we keep the time interval fixed, namely \( \Delta t = 10 \) years, and vary the amount of anisotropy by considering values of \( \epsilon \) between \( 10^{-6} \) and \( 10^{-4} \). Also in this case we find a linear dependence of the parallax angle on the varied parameter. In Fig. 6 we plot the angular dependence of the parallax for different values of anisotropy, and in Fig. 7 we plot the parallax as a function of anisotropy for a fixed direction.

After repeating the interpolation for all our data points for both the time and the anisotropy dependence we show our main result in Fig. 8. The two methods give consistent results, strengthening our confidence in the correctness of the linear interpolation procedure.

For the largest allowed values of \( \epsilon \) consistent with the observed anisotropy of the CMB (i.e., \( \epsilon \sim 10^{-6} \)) and for time delays on the order of 10 years, we find that the maximal cosmic parallax is on the order of \( 10^{-15} \) radians,
or equivalently $10^{-4}$ microarcseconds. This is 3 orders of magnitude smaller than the maximal cosmic parallax seen by [22] for LTB models. It is also 3 orders of magnitude smaller than the expected level of cosmic parallax from peculiar velocities alone in a $\Lambda$CDM universe [44]. In other words, the contribution to cosmic parallax in this model due to anisotropic expansion is subdominant to the contribution from peculiar velocities.

The qualitative behavior of the cosmic parallax in this model is also quite different from that of LTB models as put forth in [22]. Both LTB and Bianchi models show a sinusoidal (or at least quasisinusoidal) cosmic parallax. However, whereas LTB models exhibit a $2\pi$-periodic behavior, here we see that Bianchi models exhibit a $\pi$-periodic behavior. This is to be expected due to the symmetries of the two types of spacetimes, as alluded to earlier in the paper. The LTB spacetime is axisymmetric about an off-center observer but is not plane-symmetric about the plane normal to the symmetry axis. If we align the $z$-axis along the symmetry axis, then in spherical-polar coordinates this amounts to saying that the spacetime is invariant under changes in $\phi$ (the azimuthal angle) but has no symmetries under (nontrivial) changes in $\theta$ (the polar angle). In other words, one would expect cosmic expansion to be $2\pi$-periodic in $\theta$, which is just what was seen for the cosmic parallax in these models in [22]. The Bianchi spacetimes, on the other hand, are both axisymmetric and plane-symmetric about the plane normal to the axis of symmetry. So one would expect cosmic expansion to be

\[2\text{Here we assume that the Bianchi-I models we consider have roughly the same peculiar velocity-redshift relation as an FRW universe.}\]

FIG. 4 (color online). A sequence of cosmic parallax signals for different values of $\Delta t$ and fixed $\epsilon = 10^{-6}$. Top row, left to right: $\Delta t = 20$ yrs, $\Delta t = 80$ yrs. Bottom row, left to right: $\Delta t = 120$ yrs, $\Delta t = 200$ yrs. The signal-to-noise ratio becomes smaller as $\Delta t$ becomes smaller.

FIG. 5 (color online). Cosmic parallax as a function of $\Delta t$. Here $\epsilon = 10^{-6}$ and sources are at $z = 1$, separation angle ($\Delta \theta$) of 90 degrees.
π-periodic in θ, which is what we see for the cosmic parallax in these models.

Although here we have only considered a particular model, preliminary investigations into other models suggest that these results are robust. For example, one might consider models with other constant values for the equation of state parameter σ, a time-varying rather than constant σ, or an equation of state that takes a different form than Eq. (27). None of these modifications seem to affect the order of magnitude of the cosmic parallax (which, due to the symmetry of the metric, is the only free parameter). What this suggests is that the contribution to the cosmic parallax from viable Bianchi-I models is much smaller

FIG. 6 (color online). A sequence of cosmic parallax signals for different values of ε at Δt = 10 yrs. Top row, left to right: ε = 6 × 10⁻⁶, ε = 1.6 × 10⁻⁵. Bottom row, left to right: ε = 3.6 × 10⁻⁵, ε = 7.6 × 10⁻⁵.

FIG. 7 (color online). Cosmic parallax as a function of ε for a fixed value of Δt = 10 yrs.

FIG. 8 (color online). Estimate of the cosmic parallax for Δt = 10 years, ε = 10⁻⁶, and for sources at z = 1 with a separation angle of 90 degrees, plotted as a function of the angle between the trailing source and the symmetry axis (i.e., the angle between the leading source and the symmetry axis is advanced by 90 degrees). The two sets of plotted data correspond to interpolated values found using 100 trials for Δt spread from 5–500 years, and interpolated values found using 20 trials in ε in the 10⁻⁶–10⁻⁴ range, respectively.
CAN COSMIC PARALLAX DISTINGUISH BETWEEN ... than the contribution from viable LTB-void models. If the observed cosmic parallax deviates from what is expected in an FRW universe, it is unlikely that this is due to our living in a Bianchi-I spacetime.

V. CONCLUSIONS

In order for the standard FRW cosmology to agree with observations, the expansion of the universe must be accelerating. So far, all suggested mechanisms to drive such acceleration involve new physics; either the existence of exotic new components of the cosmic energy budget, modifications to Einstein’s theory of gravity, or a cosmological constant. Alternatively, it has been suggested that the phenomenon of cosmic acceleration is due to interpreting results in the FRW model, in fact the correct underlying cosmic geometry could be that of a void model, such as that idealized by an LTB spacetime. These models are relatively simple and make a host of predictions that can be used to either test or constrain them. One prediction that may soon be testable is cosmic parallax. For observers located 10 Mpc from the center of a 1 Gpc LTB void, this effect would have a magnitude of the order of $10^{-1} \mu$ as per decade for sources at redshift 1. Since the effect in an FRW universe (due to peculiar velocities) is expected to be roughly the same order of magnitude, one might hope to subtract the signal due to peculiar velocities from the signal due to anisotropic expansion about a point. Measuring this additional contribution to the cosmic parallax would clearly indicate a departure from FRW.

However, what is less clear is how we might interpret detection of an additional contribution to cosmic parallax.
