Strained relaxation in buried SrRuO$_3$ layer in (Ca$_{1-x}$Sr$_x$) (Zr$_{1-x}$Ru$_x$)O$_3$/SrRuO$_3$/SrTiO$_3$ System

Abstract
A novel relaxation phenomenon occurs in buried SrRuO$_3$ layers in strained (Ca$_{1-x}$Sr$_x$) (Zr$_{1-x}$Ru$_x$)O$_3$/SrRuO$_3$/SrTiO$_3$ (001) thin film system. The lightly strained SrRuO$_3$ buried layer is initially clamped by the SrTiO$_3$ substrate. After a heavily strained (Ca$_{1-x}$Sr$_x$) (Zr$_{1-x}$Ru$_x$)O$_3$ overlayer is deposited, localized strain relaxation develops in the buried layer. This is manifested by a crosshatch pattern of $\langle 100 \rangle$ corrugations on the surface, due to the slip of $\langle 100 \rangle$ $\{100\}$ threading dislocations. The phenomenon can be controlled by tuning the growth kinetics and strain energy of the overlayer.

A novel relaxation phenomenon occurs in buried SrRuO$_3$ layers in strained (Ca$_{1-x}$Sr$_x$)(Zr$_{1-x}$Ru$_x$)O$_3$/SrRuO$_3$/SrTiO$_3$ (001) thin film system. The lightly strained SrRuO$_3$ buried layer is initially clamped by the SrTiO$_3$ substrate. After a heavily strained (Ca$_{1-x}$Sr$_x$)(Zr$_{1-x}$Ru$_x$)O$_3$ overlayer is deposited, localized strain relaxation develops in the buried layer. This is manifested by a crosshatch pattern of (100) corrugations on the surface, due to the slip of (110) {110} threading dislocations. The phenomenon can be controlled by tuning the growth kinetics and strain energy of the overlayer. © 2006 American Institute of Physics

Thin films grown on lattice-mismatched substrates can undergo strain relaxation by generating threading and misfit dislocations.\textsuperscript{1,2} Subsequently, film surfaces develop a cross-hatch topography reflecting dislocation slip traces undergoing diffusional smoothing.\textsuperscript{3,4} In (100) III-V semiconductor layers on (100) substrates (e.g., InGaAs/GaAs, SiGe/Si), (110) dislocations on [111] slip planes leave (110) surface traces arranged in a 90° crosshatch grid pattern.\textsuperscript{1,5-8} Cross-hatch morphology has also been reported for SrRuO$_3$ (SRO) films deposited on (100) oriented SrTiO$_3$ (STO) substrates (misfit strain $\varepsilon_m=0.64\%$), but only in thick films (320 nm) after postdeposition annealing (8 h at 650 °C).\textsuperscript{9} Here we report the first observation of crosshatch development which relaxes a lightly strained buried layer (SRO) burdened by a heavily strained overlayer [SRO-alloyed CaZrO$_3$ (CZO)]. The relaxation occurs via (110) {110} dislocations.

Multilayer (CZO)$_{0.5}$(SRO)$_{0.5}$/SRO/STO films were grown on (001) STO substrates by laser ablation deposition using a KrF laser (λ=248 nm) emitting ~200 mJ pulses. The substrates (with miscut angles ~0.3°) were prepared per Refs. 10 and 11 to provide TiO$_2$-terminated surfaces with steps of a unit cell height (0.4 nm). A 20 nm STO layer was first deposited at 700 °C in 100 mTorr O$_2$ which grew in a step-flow manner. Next, SRO was grown under the same condition to a thickness (δ$_h$) of 30 nm, which was too thin to cause strain relaxation during either deposition or postdeposition annealing (e.g., 650 °C for 1 h). Finally, an overlayer of (Ca$_{1-x}$Sr$_x$)(Zr$_{1-x}$Ru$_x$)O$_3$ of various thicknesses (δ$_o$) and compositions (x) was deposited at various temperatures (T) and O$_2$ pressures (P) to impart additional strain energy to the (Ca$_{1-x}$Sr$_x$)(Zr$_{1-x}$Ru$_x$)O$_3$/SRO/STO system. The film thickness, lattice parameters, and full width at half maximum (FWHM) of the crystal orientations [e.g., ω scan of (002) reflection of SRO] were determined by a four-circle x-ray diffractometer (Bruker-AXS D8) using a Cu Kα source. The surface morphology was observed by atomic force microscopy (AFM).

The as-grown SRO film has a step-and-terrace structure [Fig. 1(a)]. Its out-of-plane lattice parameter ($c_h$), 0.3954 nm determined from Fig. 2(a), is larger than the stress-free lattice parameter (0.3930 nm) indicating a state of in-plane compressive strain ($\varepsilon_h$) set to match the substrate STO lattice parameter (0.3905 nm). Despite the strain, the FWHM of SRO (002) plane, 0.05°, is only slightly higher than that of the substrate (0.03°). So the SRO film was probably clamped and not yet relaxed. The subsequent overlayer deposition may take either a two-dimensional (2D) or a three-dimensional (3D) island-growth mode. Under the latter condition (e.g., $P\approx 10^{-2}$ Torr, $T=650$ °C), the buried SRO film

![Color online] AFM images of (a) SrRuO$_3$ on SrTiO$_3$ (001) substrate, with additional (Ca$_{0.5}$Sr$_{0.5}$)(Zr$_{0.5}$Ru$_{0.5}$)O$_3$ overlayer deposited at (b) 650 °C/10 mTorr to 20 nm, (c) 650 °C/1 mTorr to 20 nm, (d) 650 °C/1 mTorr to 10 nm, and (e) 650 °C/1 mTorr to 30 nm, or with (f) additional 20 nm CaZrO$_3$ overlayer deposited at 650 °C/10$^{-8}$ Torr.
typically showed a little change in $c_b$ [Figs. 2(b) and 2(c)], and the surface morphology remained flat [Fig. 1(b)]. In contrast, under the former condition (e.g., $P \approx 10^{-3}$ Torr, $T = 650$ °C), the buried film often showed a $c_b$ reduction [Figs. 2(d) and 2(e)], together with the development of a crosshatch surface pattern [Fig. 1(c)]. This suggests that crosshatch is associated with the 2D growth of a coherent overlayer which strains the system to the point of triggering relaxation in the buried layer, whereas the 3D growth of an overlayer has little effect.

To further substantiate the above claim, we have investigated the overlayer deposition under a wide range of conditions ($x$, $\delta_b$, $T$, and $P$), and documented the crosshatch observation, growth modes, and the strains in the overlayer and buried layer. Since the in-plane strain of the overlayer $\varepsilon_o$ is related to the out-of-plane strain, $\varepsilon_o' = -2\varepsilon_o/(1-\nu)$, where $\nu$ is the Poisson’s ratio, we can evaluate $\varepsilon_o'$ by $\varepsilon_o' = (c_o/c_{oo})-1$, where $c_o$ is the out-of-plane lattice parameter of the overlayer, and $c_{oo}$ its stress-free value [$c_{oo}$ (nm) = 0.4012(1-\nu)+0.3930x], given CZO lattice parameter $=0.4012$ nm. The correlations to $\delta\varepsilon_o'$ of the overlayer are shown in Fig. 3 for $P$, $T$, and the $c_b$ and FWHM of the buried layer. In all cases, it is apparent that (a) crosshatch never develops in 3D growth, (b) $\delta\varepsilon_o' > 0.4$ nm is required for crosshatch to form in 2D growth, and (c) both $c_b$ and FWHM of the buried layer are constant for $\delta\varepsilon_o' < 0.4$ nm, but $c_b$ decreases and FWHM increases for $\delta\varepsilon_o' > 0.4$ nm. (A subset of the latter correlation is shown for $\delta\varepsilon_o'$ in Fig. 2 inset; similar observations were also made when $P$, $T$, or $x$ were varied.) A causal relation between crosshatch formation, growth mode, and the $\delta\varepsilon_o'$ of the overlayer is thus established.

Several points are noteworthy. First, the 2D/3D growth mode transition typically took place at high $P$ and low $T$ [Figs. 3(a) and 3(b)], corresponding to a relatively low kinetic energy of incoming atoms and low thermal energy of adatoms, respectively. Since in 3D growth the side surfaces of islands are free of constraint, the overlayer can elastically relax despite clamping by the buried layer beneath, thus adding little driving force for strain relaxation. Second, as crosshatch develops at lower $P$ and higher $T$, its grid spacing ($l$) decreases with $\delta\varepsilon_o'$; e.g., as $\delta_b$ increases from 10 to 30 nm ($\delta\varepsilon_o'$ from 0.239 to 0.611 nm) $l$ decreases from 218 to 120 nm [Fig. 1(d) and 1(e)] indicating more strain relaxation in thicker film. Third, although $c_{oo}$ increases with decreasing $x$, the excessive mismatch of CZO ($e_m = 2.67\%$) films cannot be supported by the overlayer in coherent growth, resulting in a 2D/3D growth transition. [Fig. 1(f), where $\varepsilon_o$ of the CZO layer is only 1%.] Lastly, despite the preponderance of crosshatch formation in the present study, it was possible to grow a highly strained crosshatch-free overlayer (e.g., $x=0.1$, $\delta_b=20$ nm, and $\delta\varepsilon_o' = 0.39$ nm) by relatively low $T$ and high $P$ (e.g., 625 °C/10 −3 Torr or 600 °C/10 −2 Torr), conditions at the border of 2D/3D growth mode yet giving relatively smooth surfaces.

According to x-ray diffraction, the crosshatch grid aligns along (100) [Fig. 1(c)]. This is consistent with the operation of (110)/(110) dislocations, a dominant slip system in perovskites, depicted in Fig. 4 inset with a [010] slip trace and a dislocation with a Burgers vector $b$ of 0.552 nm. Using the method of Freund [16,17] and assuming a uniform shear modulus $\mu$ in the entire system, we can write the driving force $G$ on threading dislocation advance as

$$G = 2\mu b^2(\delta\varepsilon_o + \delta\varepsilon_b)\sin \alpha \sin \beta \left(1 + \frac{1}{1 - \nu}\right)$$

$$- \frac{\mu b^2 \sin^2 \beta}{4\pi(1-\nu)} \left(\frac{1 - \nu \cos^2 \beta}{\sin^2 \beta} \ln \left[\frac{2(\delta_o + \delta_b)}{r_o}\right] - \frac{1}{2} \frac{\cos 2\alpha + \frac{1 - 2\nu}{4(1-\nu)}}\right).$$

Here, the misfit forces due to the overlayer ($\delta\varepsilon_o$ and the buried layer ($\delta\varepsilon_b$) = misfit strain in SRO) are countered by the self-force of the dislocation with a core radius $r_o$, with
angles $\alpha$ (between the slip plane and the film normal) being 45° and $\beta$ (between the Burgers vector and the slip-plan/substrate intersection) being 90°. This equation correctly predicts a higher driving force as $\delta_{o}E_{o}$ in the overlayer increases, but the predicted critical $\delta_{o}E_{o}$ (or $\delta_{o}E_{o}'=1.17\delta_{o}E_{o}$ for $\nu=0.3$) underestimates the observed value (Fig. 3) by about a factor of 10. Such disagreement is also found in III-V semiconductors (e.g., see Fig. 2 of Ref. 3) and may be attributed to the additional driving force needed to overcome dislocation interactions. This is not surprising since each crosshatch step is typically 1–3 nm high, indicating the passage of more than one dislocation.

For (110) misfit dislocation, a grid of $l=b\sin\alpha/E_{o}$ =61.4 nm is required to fully relax the SRO layer, versus $l=15.4$ nm to fully relax an overlayer ($E_{o} \sim 2.53\%$). In this study, the smallest $l$ was 89 nm at $\delta_{o}E_{o}'=0.65$ nm, which would provide 70% relaxation in the SRO layer but only 20% in the overlayer. The amount of strain relaxation in crosshatched samples, estimated using the ratio of the required $l$ to actual $l$, is shown in Fig. 4. It makes clear that while crosshatch provides a visual signature of slip relaxation, the relaxation is mostly concentrated to the buried layer.

In summary, a novel geometry to reveal crosshatch without full strain relaxation was used to establish the strain relaxation mechanism in perovskite heterostructures. Crosshatch occurs during the 2D growth of a strained overlayer, involving (110) threading dislocations gliding on the \{101\} planes from the surface to the substrate, relaxing the buried layer but leaving most misfit strain in the overlayer intact. Visual and x-ray diffraction studies then allow an accurate determination of the relaxation condition and the dislocation system without thin-film microscopy that might alter the dislocation configurations. Crosshatch development is controlled by the growth kinetics and the strain energy of the overlayer. In a narrow processing window of mixed 2D/3D growth smooth heterostructures without crosshatch can be obtained.
