Minimizing Delay in Loss-Tolerant MAC Layer Multicast

Abstract
The goal of this correspondence is to minimize delay in real-time multiple-access channel (MAC) layer multicast by exploiting the broadcast nature of wireless medium and limited loss tolerance of the applications. Multiple transmissions of a packet at the MAC layer significantly reduces the delay than that when only one transmission is allowed. But each additional transmission consumes additional power and increases network load. Therefore, the goal is to design a policy that judiciously uses the limited transmission opportunities so as to deliver each packet in the minimum possible time to the required number of group members. The problem is an instance of the stochastic shortest path problem, and using this formulation computationally simple, closed-form transmission strategies have been obtained in important special cases.

Keywords
broadcast property, dynamic programming, threshold policies, wireless multicast

\[ \pm 2^{k+1} \text{ and } S(a) \text{ is an integer, only two of the four sign combinations are possible, leading to } S(a) = -2^k \text{ or } S(a) = 2^k. \]

The preceding three cases give in total the four possible values 0, \pm 2^k, \pm 2^{k+1} for \( S(a) \). Suppose the cross-correlation function \( C_{ij}(t) \) takes on the value zero \( r \) times, the value \( 2^k \) is taken on \( s \) times, the value \(-2^k \) occurs \( t \) times, and the value \(-2^{k+1} \) occurs \( v \) times. From Lemmas 1 and 2, it follows that

\[
\begin{align*}
    r + s + t + v & = 2^k - 1 \\
    s - t - 2v & = 1 \\
    s + t + 4v & = 2^k - 1.
\end{align*}
\]

Since \( S(a) = \pm 2^k \) is only possible in Case 2c, which occurs \( (2^k + 1)/3 \) times, we get \( s + t = (2^k + 1)/3 \). The last equation leads to \( r = (2^{k-1} - 1)/3 \) and therefore the first equation implies \( r = 2^{k-1} - 1 \). Finally, the last two equations give \( t = 0 \) and \( s = (2^k + 1)/3 \).

VI. CONCLUSION

We have found a new pair of \( m \)-sequences of different periods \( 2^m - 1 \) and \( 2^k - 1 \) where \( m = 2k \) with three-valued cross correlation and we have completely determined the cross-correlation distribution. The pair of sequences differ by the sequences in the Kasami family in that we replace the decimation \( d = 1 \) by the decimation \( d = 2^i - 1 \) where \( k \) is an odd integer and \( i = (k + 1)/2 \).

Minimizing Delay in Loss-Tolerant MAC Layer Multicast

Prasanna Chaporkar and Saswati Sarkar, Member, IEEE

Abstract—The goal of this correspondence is to minimize delay in real-time multiple-access channel (MAC) layer multicast by exploiting the broadcast nature of wireless medium and limited loss tolerance of the applications. Multiple transmissions of a packet at the MAC layer significantly reduces the delay than that when only one transmission is allowed. But each additional transmission consumes additional power and increases network load. Therefore, the goal is to design a policy that judiciously uses the limited transmission opportunities so as to deliver each packet in the minimum possible time to the required number of group members. The problem is an instance of the stochastic shortest path problem, and using this formulation computationally simple, closed-form transmission strategies have been obtained in important special cases.

Index Terms—Broadcast property, dynamic programming, threshold policies, wireless multicast.

I. INTRODUCTION

In wireless networks, many real-time applications such as conference meetings, emergency operation in case of a natural disaster, and military operations require one to many (multicast) communication. Real-time applications can tolerate some packet loss but require low delay. Our contribution is to develop transmission schemes that minimize the delay in real-time medium access control (MAC) layer multicast by exploiting the limited loss tolerance and the broadcast property of wireless medium. Most of the work in wireless multicast has focused on the network and transport layers, e.g., [5], [8], [12]. Though the performance of the network and transport layer protocols depends on the efficiency of the MAC layer strategy, MAC layer multicast has not been adequately explored. Our work is directed towards filling this void.

Now, we describe the challenges in minimizing the delay attained by MAC layer multicast schemes. Due to the broadcast property of wireless communication, a sender can deliver a packet to all its receivers which are in its transmission range using a single transmission. Apparently, this broadcast nature can be used to reduce the delay at the MAC layer. But, the broadcast nature also introduces critical challenges. A multicast specific challenge is that some but not all the receivers may be ready to receive due to the interference in their neighborhood and transmission quality in wireless channels. Consider a MAC layer multicast session from a sender \( S_1 \) to receivers \( R_1 \) to \( R_3 \) which are in \( S_1 \)'s transmission range (Fig. 1). When \( S_2 \) is transmitting, \( R_1 \) and \( R_2 \) cannot receive a transmission from \( S_1 \) as both the transmissions will collide at these receivers. However, \( R_3 \) and \( R_4 \) can still receive the transmission.
We investigate the tradeoff between loss and delay for MAC layer multicast. Specifically, we study the problem of minimizing the mean delay to deliver an HoL packet to $Z$ out of total $G$ receivers using at most $K$ transmissions. The parameters $Z$ and $K$ depend on loss tolerance of the application and power constraints, respectively. In Sections II and III, we describe the system model, and formulate the optimization goal as a stochastic shortest path (SSP) problem, respectively [2], [3]. The time and memory required by the SSP formulation increases exponentially with increase in $G$. Next, using the SSP formulation, we show that the computation time and the storage requirements of the optimal policy are polynomial in $G$, $K$, $Z$ when the readiness states of different receivers constitute mutually independent and identically distributed Markov processes (Section IV-A). Next, we consider two extreme cases of the above independent and identically distributed (i.i.d.) Markovian receiver readiness process: the readiness process of each receiver is 1) bursty, i.e., the transition probabilities of the MC are small (Section IV-B), and 2) Bernoulli (Section IV-C). In both these cases, we prove that the optimal policy is threshold-type, and the storage requirements and the computation time for the optimal thresholds are polynomial in $G$, $K$, $Z$. In Section V, we discuss several salient features of the policies and evaluate their performances numerically and using simulations. We present all proofs in the Appendix.

We briefly review the MAC protocols for multicast in ad hoc networks. IEEE 802.11 supports MAC layer multicast by disabling the control message exchange and broadcasting the data packets; the protocol is not therefore reliable. Tang et al. have proposed to enhance the reliability of IEEE 802.11 by a) using the capture mechanism to ensure that at least one receiver is ready when the packet is broadcast [10], and b) by transmitting a packet to each receiver separately in unicast mode [11]. The first scheme may not provide desired loss rates, and the second scheme does not exploit the broadcast property.

II. SYSTEM MODEL

We consider a single multicast session with $G$ receivers. The impact of the network and the channel errors on the multicast session is that the receivers are not always ready to receive. This may happen because of a transmission in the neighborhood of a receiver, bursty channel errors, or power-saving operation of a receiver. Thus, the receiver readiness states are correlated in the same time slot, and across the time slots. We model the readiness process of all the receivers as a Markov chain (MC) with an arbitrary transition probability matrix (TPM) $\tilde{B}$. A state of the MC is the $G$-dimensional readiness vector $\mathbf{j} = [j_1, j_2, \ldots, j_G]$, where the component $j_i$ is 1 if the $i$th receiver is ready and 0 otherwise.

Let $C^i$ denote the state space of the MC. We assume that $2^C \times 2^C$ TPM $\tilde{B}$ is irreducible, aperiodic, and time-homogeneous. We adopt this model because in a distributed environment the senders do not coordinate their transmissions, and only observe the readiness states of their receivers. Thus, from the perspective of a sender, the network is a stochastic disturbance which is not controllable but only partially observable. The arbitrary Markovian transitions of the readiness process allow us to consider different network loads and different inter-session interactions.

A sender queries the readiness states of the receivers by transmitting control packets, and decides whether to transmit a packet depending on the transmission strategy and result of the query. Every receiver maintains its readiness state throughout the transmission. This assumption is justified because the time scale of a change of transmission quality is much larger than the duration of packet transmission. Also, the level of interference does not change during a packet transmission, since in several MAC protocols (e.g., IEEE 802.11), the exchange of control messages prevents a new transmission during an ongoing transmission in the reception range of the receiver. The sender backs off for a random
duration before querying the system again, irrespective of the transmission decision, so as to allow other senders to use the shared medium. The structure of the multiple-access protocol described above is similar to IEEE 802.11. Note that the receiver readiness process is Markovian only when restricted to the slots in which the sender queries or backs off, e.g., in duration $[T_i, T_{i+1}] \cup X_3 \cup T_{i+1} \cup X_1$ in Fig. 2.

We assume that time is slotted. The packet transmission times and backoff durations are i.i.d. random variables with arbitrary probability distributions and finite expected values $E[V]$ and $E[X]$. For brevity, let $\bar{X} = E[X] + 1$ and $\bar{V} = E[V + X] + 1$. The slots in which the sender queries the readiness states are called sample points, and the readiness process observed by the sender is called sampled readiness process. Note that the sampled readiness process is also an irreducible, aperiodic and time-homogeneous MC. Let $\mathbf{B}$ denote the TPM for the sampled readiness process. Then, the transition probabilities of the sampled readiness process are

$$B_{i,j} = \sum_{l=1}^{\infty} B^{(l)}_{i,j} \mathbf{P} \{ X = l - 1 \}$$

where $B^{(l)}_{i,j}$ is the probability of being in state $j$ starting from state $i$ after $l$ transitions of the original readiness process. At any time, a receiver is satisfied if it has received the packet in prior transmissions; otherwise, it is unsatisfied. Initially, every receiver is unsatisfied and with subsequent transmissions some receivers become satisfied.

III. A FRAMEWORK FOR COMPUTING THE OPTIMAL TRANSMISSION POLICY

Our goal is to design a transmission strategy that minimizes the expected time to deliver an HoL packet to at least $Z$ receivers using at most $K$ transmissions. This optimization can be formulated as a stochastic shortest path problem (SSP) as follows. Let $\mathcal{E} = \{a_1, a_2, \ldots, a_G\}$ where $a_i$ is 1 if receiver $i$ is satisfied, and 0 otherwise. The system state is the vector $(k, \bar{a}, \bar{j})$, where $k$ is the number of completed transmissions and $\bar{j}$ is the readiness vector. Note that when $k = 0$, then $\bar{a} = 0$, where $0$ is the $G$-dimensional vector of zeros. In every state $(k, \bar{a}, \bar{j})$, the sender can either back off or transmit. If the sender backs off, then the state becomes $(k, \bar{a}, \bar{j} + 1)$ w.p. $B_{i,j}$. If the sender transmits, then the state becomes $(k + 1, j + \bar{a} \bar{a}, \bar{j} + 1)$ w.p. $B_{i,j}$. Clearly, for every termination state $(k, \bar{a}, \bar{j})$ (states with $\sum_{i=1}^{G} a_i \geq Z$), $J^*(k, z, t) = 0$. If after $K - 1$ transmissions the number of satisfied receivers $z$ is less than $Z$, then the sender transmits only if $Z - z$ or more unsatisfied receivers are ready. Thus, the process always terminates. Also,

$$J^*(K - 1, \bar{a}, \bar{j}) = \bar{V} + \delta_{\bar{a}, \bar{j}}, \quad \text{if } \sum_{i=1}^{G} a_i < Z \quad (1)$$

where

$$J^* = \left\{ j : \sum_{i=1}^{G} a_i \circ j_i \geq Z \right\}$$

and $\delta_{\bar{a}, \bar{j}}$ denote the product of $\bar{X}$ and the expected number of sample points required to reach any of the states $j \in J^*$ for the first time starting from $j$ in the receiver readiness process.

Let $J^*_f(k, \bar{a}, \bar{j})$ and $J^*_b(k, \bar{a}, \bar{j})$ denote the minimum expected termination time from $(k, \bar{a}, \bar{j})$ if the control decision is to transmit and back off, respectively. For convenience, we assume that $J^*(K, \bar{a}, \bar{j}) = \infty$ if $\sum_{i=1}^{G} a_i < Z$; note that the system never reaches these states. The minimum expected termination times from the states with $\sum_{i=1}^{G} a_i < Z$, $k \leq K - 1$, satisfy the following Bellman’s equations:

$$J^*_f(k, \bar{a}, \bar{j}) = \min \{ J^*_f(k, \bar{a}, \bar{j}), J^*_b(k, \bar{a}, \bar{j}) \} \quad (2)$$

$$J^*_b(k, \bar{a}, \bar{j}) = \bar{V} + \sum_{j \in \mathcal{E}} B_{i,j} J^*(k + 1, \bar{a} + \bar{j} + 1) \quad (3)$$

$$J^*_{ib}(k, \bar{a}, \bar{j}) = \bar{X} + \sum_{j \in \mathcal{E}} B_{i,j} J^*_b(k, \bar{a} + \bar{j} + 1). \quad (4)$$

If $J^*(k, \bar{a}, \bar{j}) = J^*_b(k, \bar{a}, \bar{j})$, then the optimal decision in state $(k, \bar{a}, \bar{j})$ is to back off; otherwise, the optimal decision is to transmit. Thus, the optimal strategy can be obtained by solving the Bellman’s equations (2)-(4).

Bellman’s equations can be solved using several standard methods, among which the Linear Programming method [3] has the least complexity. In this method, we need to solve a linear program in which the number of variables and constraints are of the order of the number of system states which is $K^{2G}$ in this case. Thus, the complexity of this method is $O((K^{2G})^{-3/5})$ [6]. Once the optimal policy is computed, online transmission decisions can be made using a lookup table which needs to store all $O(K^{2G})$ system states. Thus, both the time and the memory required for computing and executing the optimal strategy increases exponentially with increase in $G$.

IV. OPTIMAL TRANSMISSION STRATEGIES IN SPECIAL CASES

We now consider the special case that the receiver readiness states evolve as per i.i.d. Markovian readiness processes. Specifically, each receiver’s readiness process at the sample points evolves as per a two-state Markov process (Fig. 3), which changes state from ready (not ready) to not ready (ready) with probability $1 - \delta(1 - \gamma)$. The readiness states of different receivers are mutually independent and identically distributed. We obtain an optimal policy whose computational complexity is $O(KG^2)$ and memory requirement is $O(KG^2)$; both time and memory requirements therefore increase polynomially with increase in $K$ and $G$ (Section IV-A).

We next consider two extreme scenarios of i.i.d. Markovian readiness processes: a) bursty readiness process $(1 - \gamma \approx 1)$, and b) Bernoulli readiness process $(1 - \gamma = \delta)$. We prove in Sections IV-B and C that in both these extreme cases, the optimal strategies are...
threshold-type\(^1\) and have lower computation time (\(O(KG^2)\) for bursty readiness process, and \(O(KG^2)\) for Bernoulli readiness process) and lower memory requirements (\(O(KG)\)) than that for arbitrary i.i.d. Markovian readiness processes. In threshold-type transmission policies, before each transmission, the sender selects a threshold and transmits only when the number of unsatisfied ready receivers exceeds the selected threshold. We show that the optimal threshold for each transmission depends on the number of transmissions utilized so far and the number of receivers that have already received the packet, and can be computed in \(O(KG^2)\) and \(O(KG^2)\) times for bursty and Bernoulli readiness processes, respectively.

A. I.I.D. Markovian

We now consider i.i.d. Markovian readiness processes. Since the readiness states are i.i.d., intuitively, the expected time for termination does not depend on identity of the satisfied or unsatisfied receivers, but rather depends only on the number of satisfied receivers \(z\) and the number of unsatisfied ready receivers \(t\). We prove this formally in the following lemma. Let \(z\) denote the number of satisfied receivers, and let \(t\) denote the number of unsatisfied receivers, and let \(\bar{z}, \bar{t}\) denote the number of unsatisfied ready receivers in state \((\bar{z}, \bar{t})\), i.e.,

\[
z = \sum_{i=1}^{G} z_i, \text{ and } t = \sum_{i=1}^{G} t_i.
\]

**Lemma 1:** Let in system states \((\bar{z}, \bar{t})\) and \((\bar{z}, \bar{t})\),

\[
z = z_1 \text{ and } t = t_1 + t_2.
\]

Then, for an i.i.d. Markovian receiver readiness process

\[
J^*(k, \bar{z}, \bar{t}) = J^*(k, \bar{z}, \bar{t}), \quad \text{for every } k \in \{0, \ldots, K\}.
\]

From Lemma 1, it suffices to consider the system state as \((k, z, t)\). Thus, the number of system states is \(O(KG^2)\). Since in each state there are only two possible actions (transmission and backoff), the memory required for storing the optimal policy is also \(O(KG^2)\).

Another important consequence of Lemma 1 is that the expected termination time depends on the initial readiness vector only through the initial number of ready receivers. Hence, when the initial number of ready receivers is \(t\), we refer to the problem of minimizing the above expected time as \(P(K, G, Z, T)\). We now describe how \(P(K, G, Z, T)\) can be solved in polynomial time.

We now consider the aggregate readiness process of receivers. The state of the aggregate readiness process is the number of ready receivers (Fig. 4). Clearly, the aggregate readiness process is a Markov process. The transition probability in the aggregate readiness process of \(G - z\) receivers, \(P_{r_1}(z)\), denotes the probability that \(r_1\) receivers are ready at the current sample point given that \(t\) out of \(G - z\) receivers were ready at the previous sample point. Then, for all \(t, r_1 \in \{0, \ldots, G - z\}\)

\[
P_{r_1}(z) = \sum_{u=0}^{t} \binom{t}{u} \delta(1 - \delta)^{t-u} \times \left( (G - z - t) \frac{1}{t - u} \right)^{\gamma(1 - \gamma)^{t-u} \gamma^{-1} t_1 + u}.
\]

Here, \((\gamma) = 0\) if \(\gamma < 0\) or \(\gamma > 1\). If the sender backs off in state \((k, z, t)\), then the state changes to \((k, z, t)\) w.p. \(P_{r_1}(0)\), and if the sender transmits in state \((k, z, t)\), then the state changes to \((k + 1, z + t, t_1)\) w.p. \(P_{r_2}(z + t)\).

The policy \(\pi(K, Z)\) comprising of control decisions \(\{D_{k,z,t}\}\) for \(K, Z\) computed in Fig. 5 solves \(P(K, G, Z, T)\) for all \(t\). The algorithm in Fig. 5 first solves \(P(1, G - z, Z - z, t_1)\) for all \(z, t_1\) using (1). Subsequently, it progressively solves \(P(k, G - z, Z - z, t_1)\) for all \(z, t_1\) and \(k = 2, 3, \ldots, K \) by solving the linear program LP1 in Fig. 5. Now, (B3) in Fig. 5 obtains the optimal decisions in every state \((k, z, t)\) as the optimal decision \(D_{k,z,t}\) is to transmit (back off, respectively) in state \((k, z, t)\) if and only if \(J^*(k, z, t) < (\geq, \text{resp}.) J^*(k, z, t)\).

**Theorem I:** For every \(k \leq K - 1\), and \(z, t\), \(J^*(k, z, t) = J^*(k, z, t)\). For every \(t = 0, \ldots, G, \pi(K, Z)\) solves \(P(K, G, Z, T)\).

Finally, \(\pi(K, Z)\) is computed in Fig. 5 by solving \(O(K)\) linear programs each with \(O(G^2)\) variables and constraints. Thus, \(\pi(K, Z)\) can be computed in \(O(KG^2)\) time [6].

B. Subcase 1: Bursty Receiver Readiness States

We consider a special case of i.i.d. Markovian readiness process in which the receiver readiness states are bursty, i.e., the transition probabilities \(1 - \delta\) and \(1 - \gamma\) are close to zero. From (7), we observe that if \(t \geq 2\), then \(P_{r_1}(0) \approx 0\) as it only contains terms with higher powers of \((1 - \delta)\) and \((1 - \gamma)\) for every \(z \in \{0, \ldots, G\}\). Now, for \(u \in \{t - 1, t, t + 1\}\) and \(t \in \{0, \ldots, G - z\}\)

\[
P_{r_1}(z) \approx \alpha_{t_1}(z) \approx (G - t - z) \delta(1 - \delta)^{-1} \gamma^{-1} t_1 + u.
\]

Thus, the aggregate receiver readiness process can be approximated as a nonhomogeneous birth–death (BD) process (Fig. 6). Let \(t\) be the number of ready, unsatisfied receivers right after the \(k\)th transmission, for \(k \geq 1\). Let \(t_0\) be the number of ready receivers when the packet reaches the HoL position. Using the BD approximation, we obtain a closed-form computationally simple optimal transmission strategy, \(\pi_1(K, Z)\) (Fig. 7). We prove that the optimal transmission decision in any state \((k, z, t)\) is to transmit if and only if \(t > t_0\) is greater than or equal to a threshold \(\tau(k, z)\), if \(k \geq 1\) and \(t_0\) has one of two values that depend on \(t_1\), if \(k = 0\). Thus, the optimal policy can be stored as a function of \(k\) and another variable \(\tau\) or \(t_0\) that has \(G + 1\) possible values; this requires \(O(KG)\) memory.

We first explain why the transmission policy at \(k = 0\) differs from that at other values of \(k\). Note that \(t_0 \in \{0, \ldots, G\}\), while \(t_1 \in \{0, 1\}\), for \(k \geq 1\). Let \(r\) receivers be satisfied after \(k\) transmissions and let \(T_{k,r}\) denote the set of aggregate readiness states in which the optimal decision is to transmit

\[
T_{k,r} = \{t : 0 \leq u < G - z \text{ and } J^*(k, z, t) < J^*(k, z, t)|\}
\]

Let \(m_{k,r}\) denote the smallest member of \(T_{k,r}\). Clearly, \(m_{k,r} \geq 1\) for every \(k\) and \(z\). Let \(k \geq 1\). Since \(t_1 \in \{0, 1\}\), \(t_2 \leq m_{k,r}\). Thus,
Procedure Optimal_Policy_Computation($K, Z$) begin

\[ s'_t(z) \text{ Def } = \text{ the product of } X_t \text{ and the expected number of sample points to visit a state } u \geq \hat{t} \text{ for the first time from state } t \text{ in the aggregate readiness process of } G - z \text{ receivers.} \]

Note: \[ s'_t(z) = 0 \text{ for every } t \geq Z - z. \]

\[ D_{k,z,t} \text{ Def } = \text{ the control decision in state } (k, z, t). \]

Initialize: \[ (B1) \hat{J}^*(k, z, t) = 0 \text{ for every } k, \text{ and } z \geq Z, \]

\[ (B2) \hat{J}^*(K - 1, z, t) = V + s'_{t+1,z}(z) \text{ for every } z < Z, \text{ and } 0 < t < T, \]

\[ D_{K-1,z,t} = B \text{ if } z + t < Z, \text{ and } D_{K-1,z,t} = T \text{ otherwise.} \]

for \((k = K - 2 \text{ to } 0)\) do solve the following LP.

LP1: Maximize: \[ \sum_{z=0}^{G-1} \sum_{t=0}^{G-t} \hat{J}(k, z, t) \]

Subject to:

1. \[ \hat{J}(k, z, t) \leq \hat{J}_T(k, z, t) \]
2. \[ \hat{J}_T(k, z, t) = V + \sum_{z=0}^{G-t} P_{t,z}(z + t) \hat{J}(k + 1, z + t, t) \text{ for every } z < Z \text{ and } t < G - z, \]
3. \[ \hat{J}(k, z, t) \leq \hat{J}_B(k, z, t) \]
4. \[ \hat{J}_B(k, z, t) = X + \sum_{t=0}^{G-z} P_{t,z}(z) \hat{J}(k, z, t) \text{ for every } z < Z \text{ and } t < G - z. \]

Let \( \hat{J}^*(k, z, t) \), \( \hat{J}_T^*(k, z, t) \) and \( \hat{J}_B^*(k, z, t) \) denote the optimal solution of LP1.

(B3) \( D_{k,z,t} = T \) if \( \hat{J}_T^*(k, z, t) < \hat{J}_B^*(k, z, t) \), and \( D_{k,z,t} = B \) otherwise.

Policy \( \pi(K, Z) \) transmits in state \((k, z, t)\) if \( D_{k,z,t} = T \); it backs off otherwise.

end

Fig. 5. Pseudocode for the optimal transmission policy, \( \pi(K, Z) \), when the receiver readiness processes are i.i.d. Markovian.

due to its BD nature, starting from \( t_k \), the aggregate readiness process of unsatisfied receivers cannot reach states greater than \( m_{k,z} + 1 \) before \( m_{k,z} \). Thus, the optimal policy transmits when \( m_{k,z} \) unsatisfied receivers are ready (see Fig. 8(a)). This explains the existence of optimal thresholds in this case. But, \( t_0 \) can exceed 1. Hence, \( m_{0,z} \) may be less than \( t_0 \). Thus, the optimal policy transmits when either \( u_1 \) or \( u_2 \) unsatisfied receivers are ready, where \( u_1 \) is the largest element of \( T_{01} \), such that \( u_1 < t_0 \), and \( u_2 \) is the smallest element of \( T_{02} \), such that \( u_2 > t_0 \) (see Fig. 8(b)). Thus, for \( k = 0 \), the optimal strategy may not be threshold-type, and the minimum expected termination time is the minimum of the expected termination times in the cases that \( m_{0,z} \geq t_0(\{J_1(0, 0, t)\}) \) and \( m_{0,z} < t_0(\{J_0(0, 0, t)\}) \) (Fig. 7).

\( \pi_1(K, Z) \) in Fig. 7 first computes \( \hat{J}(K - 1, z, t_k-1) \) for \( z \leq G, \quad t_k-1 \in \{0, 1\} \), and the optimal threshold \( \tau(K - 1, z) \) from (1) and the BD nature of the aggregate readiness process ((C1) and (C2)). Subsequently, it sequentially computes, \( \hat{J}(k, z, t_k) \) for \( z \leq G, t_k \in \{0, 1\} \), and the optimal threshold \( \tau(k, z) \) for \( k = K - 2, K - 3, \ldots, 1 \) ((C3), (C4), and (C5)). Finally, it computes \( \hat{J}(k, z, t) \) for \( z \leq G, t_k \in \{0, \ldots, G\} \), and the possible transmission states \( \tau(t_k) \) ((C6) and (C7)). We prove that these \( \hat{J}(k, z, t) \) equal corresponding values of \( J(k, z, t) \) (Appendix B). \( \pi_1(K, Z) \) can be computed in \( O(\{G\}) \) time.

Theorem 2: Let the aggregate receiver readiness processes of unsatisfied receivers be a BD process. Then, \( \pi_1(K, Z) \) solves \( P(K, Z, t) \) for every \( t \in \{0, \ldots, G\} \).

Note that the BD modeling is an approximation for i.i.d. Markovian processes for low values of \( 1 - \gamma \) and \( 1 - \delta \). We now evaluate the error due to this approximation. Let \( D_{O} \) denote the minimum expected delay obtained using the policy in Fig. 5. Let \( D_{A} \) denote the expected delay obtained using the policy in Fig. 7. In Fig. 9, we plot the percentage normalized approximation error \( \frac{D_{A}}{D_{O}} \times 100 \) as a function of \( 1 - \delta \). This normalized approximation error turns out to be 0 for small values of \( 1 - \delta \) and it is less than 2% for \( 1 - \delta \leq 0.3 \). This validates the BD approximation. Note that when the readiness states are generated by a Raleigh-fading channel which is good for 99% of the time and has mean fade duration of 10 slots, then \( 1 - \delta = 0.001 \) and \( 1 - \gamma = 0.1 \) [9].

C. Subcase 2: Bernoulli Readiness States

Now, we assume that the receiver readiness states are i.i.d. Bernoulli, i.e., in a slot, a receiver is ready w.p. \( p \). Now, \( P_{k}(z) \) does not depend on \( t_i \), as the readiness states are independent across the slots. Thus, it suffices to maintain a two-dimensional system state \( (k, z) \) and hence the memory required for executing the optimal policy is \( O(\{K\}) \). Also, now the aggregate readiness process can have transitions to nonadjacent states (Fig. 4). The optimal transmission algorithm \( \pi_2(K, Z) \) (Fig. 10) is, however, still threshold type, and can be computed in \( O(\{K\}) \) time.

Theorem 3: For i.i.d. Bernoulli receiver readiness processes \( \pi_2(K, Z) \) solves \( P(K, Z, t) \) for every \( t \in \{0, \ldots, G\} \).
Fig. 6. A BD process that approximates the aggregate receiver readiness process of \(G - z\) unsatisfied receivers when the receivers have bursty i.i.d. Markovian readiness processes.

Procedure Threshold_Computation_1(\(K, Z\))
begin
\(s_{u, v}(z) \triangleq \text{the product of } \bar{X} \text{ and the expected number of sample points to reach state } v \text{ from state } u \text{ for the first time in the BD process of } G - z \text{ unsatisfied receivers.}\)
\(s_{u, v_1 || v_2}(z) \triangleq \text{the product of } \bar{X} \text{ and the expected number of sample points to reach either state } v_1 \text{ or state } v_2 \text{ from state } u \text{ for the first time in BD process of } G - z \text{ unsatisfied receivers.}\)

\(\hat{\tau}(t) = \{\hat{u}_1, \hat{u}_2\} \text{ such that } J_2(0, 0, t) = s_{1, \hat{u}_1 || \hat{u}_2}(0) + \sum_{i=1}^{\hat{u}_2} J_r^*(0, 0, \hat{u}_i)\).
\(\hat{J}_r^*(0, 0, t) = \min(J_1(0, 0, t), J_2(0, 0, t)).\)
end
Procedure Transmission_Strategy_1(\(K, Z\))
begin
if (\(k = 0\) and \(K > 1\)) then
if \(t_0 = t\) then \(\pi_1(K, Z)\) transmits in states \((0, 0, u)\), where \(u \in \hat{\tau}(t_0)\).
else
\(\pi_1(K, Z)\) transmits in state \((k, z, \tau(k, z))\).
end
V. Performance Evaluation and Discussion

We first discuss how \(Z\) can be chosen based on application requirements. The loss at a receiver is the fraction of packets transmitted by the sender which the receiver does not receive, and the system loss is the sum of the losses of the receivers. Usually, higher layer applications and coding schemes (e.g., digital fountain [4]) require that the loss at each receiver be upper-bounded by a constant. In several cases,
Fig. 8. The aggregate readiness process of unsatisfied receivers. The shaded states are in $T_{b_{u_1}}$. Let the process be in state $t$. In case a), $m_{b_{u_1}} = u > t$, and in case b) $m_{b_{u_1}} \leq u_1 < t$. The optimal policy transmits when (a) $u$ unsatisfied receivers are ready in case a), and (b) when either $u_1$ or $u_2$ receivers are ready in case b).

Fig. 9. The normalized approximation error ($\frac{D_A - D_M}{D_A} \times 100\%$) introduced due to the BD approximation in the computation of the minimum expected delay as a function of the transition probability $1 - \delta$. In case 1, $\gamma = \delta$. In case 2, $\gamma = 0.9$. Here, $G = Z = 10$, $EV = 100$ slots, and $K = 5$.

```
Procedure Threshold_Computation_2(K, Z)
begin
    $\tilde{p}_u(z) \equiv$ the probability that $u$ out of $G - z$ receivers are ready.
    $q_{u_1,u_1}(z) \equiv$ the probability that $u_1$ out of $G - z$ unsatisfied receivers are ready given
    that $u_1 \geq u$.
    For every $z \in \{1, 2, \ldots, G\}$
        (D1) $G^*(K - 1, z) = \frac{X}{p_{G - z}(z)} + V$ if $z < Z$ and
             $= 0$ o.w.
        (D2) $\tau(K - 1, z) = Z - z$ if $z < Z$;
    for $(k = K - 2$ to $1)$ do
        for $(z = 1$ to $Z)$ do
            (D3) $G^*(k, z) = \min_{0 \leq u \leq Z - z} \left\{ \frac{X}{\tilde{p}_u(z)} + \sum_{v=0}^{G-z} q_{u,v}(z) G^*(k+1, z+v) \right\}$
                $+ V$;
            (D4) $\tau(k, z) \in \arg \min_{0 \leq u \leq Z - z} \left\{ \frac{X}{\tilde{p}_u(z)} + \sum_{v=0}^{G-z} q_{u,v}(z) G^*(k+1, z+v) \right\}$
        end
    end
Procedure Transmission_Strategy_2(K, Z)
begin
    Initialize the system state $(k, z) = (0, 0)$.
    while $(z < Z)$ do
        Transmit when the number of unsatisfied ready receivers (say $r$) is greater than or
        equal to $\tau(k, z)$.
        Update the system state after transmission as follows: $k = k + 1$ and $z = z + r$.
    end
```

Fig. 10. Pseudocode for the optimal transmission policy, $\tau_2(K, Z)$, when the receiver readiness processes are i.i.d. Bernoulli.
retrieving a lost packet from another receiver is easier than retrieving a lost packet from the sender, e.g., when the distance between different receivers is significantly lower than that between the sender and any receiver. In such scenarios, the applications require upper bounds on the system loss. The policies presented in this correspondence guarantee that the system loss is upper-bounded by $G - Z$. When the receiver readiness process is i.i.d. Markovian, the policies also ensure that the loss at each receiver is upper-bounded by $(G - Z)/G$ with probability 1. Thus, in these cases, $Z$ can, respectively, be determined from the system loss requirements and the loss tolerance at the individual receivers. When the receiver readiness processes are not i.i.d., loss guarantees can only be obtained for individual receivers by including explicit constraints related to such requirements in the Markov decision process (MDP) formulation. We expect that the complexity of solving such a constrained MDP will be exponential in $G$ and $K$ [1].

We now evaluate the performance of the proposed policies using numerical computations. Fig. 11 demonstrates that the expected delay significantly decreases as $K$ increases for small $K$, and saturates with further increase in $K$. Fig. 11 also shows that the minimum expected delay is significantly lower for 5% loss tolerance at each receiver (i.e., 100 * $(G - Z)/G = 5$), than that for zero loss tolerance ($Z = G$). Thus, a small number of transmissions and a small loss tolerance are usually sufficient to achieve the minimum expected delay.

We have so far assumed that the receiver readiness states are Markovian and are not affected by the transmission policies. Next, using simulations, we demonstrate that the resulting intuition and performance trends carry over to actual networks where these assumptions may not hold. We consider a simple symmetric topology shown in Fig. 12(a), where the readiness states are generated by packet transmissions. We model the readiness process for each receiver as a BD Markov process and estimate $\gamma$ and $\delta$ from the readiness states. We subsequently obtain the transmission policy using these estimates, $Z = G$, and the algorithm proposed in Fig. 7. In this simple example, the receiver readiness states generated by the above transmissions turn out to be ergodic. Thus, node $M$ can estimate the transition probabilities of the readiness states from observations, e.g., by updating the estimates of the transition rates every time it samples the readiness states of the receivers. Next, for moderate values of $\lambda_M$, like in Fig. 11, the proposed policy can significantly reduce the delay for multiple transmissions ($K = 3$) than when only one transmission ($K = 1$) is allowed (see Fig. 12(b)). Finally, we compare the performance of the proposed policy with a naive heuristic. In this heuristic, which we refer to as threshold-1 policy, $M$ transmits when a) at least one unsatisfied receiver is ready for the first $K - 1$ transmissions and b) all the unsatisfied receivers are ready for the last transmission. The proposed policy achieves significantly smaller delay than the threshold-1 policy (see Fig. 12(c)).
Fig. 12(c). Proving that the receiver readiness states are ergodic and designing computationally tractable optimal policies in arbitrary networks constitutes interesting problems for future research.

Finally, the computation time and storage requirements of the optimal policies $\pi(K, Z), \pi_1(K, Z), \pi_2(K, Z)$ are exponential in the input size in all cases, as the input size is $O(G)$ in the general case and $O(\log(G))$ when the receiver readiness states are i.i.d. Markovian. An interesting direction of future research is to determine whether the delay minimization problem is NP-hard.

APPENDIX A

VALUE-ITERATION APPROACH

We will prove the optimality results using the value-iteration approach that is used for solving the Bellman’s equations [3]. We now describe the value iteration approach. Let $J_i(k, \bar{a}, \bar{j}), J_{i,T}(k, \bar{a}, \bar{j}),$ and $J_{i,H}(k, \bar{a}, \bar{j})$ be defined iteratively as follows. For every $0 \leq k \leq K - 1$ and $\bar{a}, \bar{j} \in \mathcal{C}$ such that $\sum_{i=1}^{G} a_i < Z$

\[
J_i(k, \bar{a}, \bar{j}) = \min \{ J_{i,T}(k, \bar{a}, \bar{j}), J_{i,H}(k, \bar{a}, \bar{j}) \}
\]

\[
J_{i,T}(k, \bar{a}, \bar{j}) = \bar{V} + \sum_{\bar{j} \in \mathcal{C}} B_{\bar{j}} J_{i-1}(k + 1, \bar{a} \circ \bar{j}, \bar{j}_1)
\]

\[
J_{i,H}(k, \bar{a}, \bar{j}) = \bar{X} + \sum_{\bar{j} \in \mathcal{C}} B_{\bar{j}} J_{i-1}(k, \bar{a}, \bar{j}).
\]

For termination states $(k, \bar{a}, \bar{j})(\sum_{i=1}^{G} a_i \geq Z)$

\[
J_i(k, \bar{a}, \bar{j}) = J_{i,T}(k, \bar{a}, \bar{j}) = J_{i,H}(k, \bar{a}, \bar{j}) = 0
\]

for every $l$. Moreover, $J_i(k, \bar{a}, \bar{j}) \rightarrow \infty$ if $\sum_{i=1}^{G} a_i < Z$ for every $l$.

For all $0 \leq k \leq K - 1$,

\[
J_{0,T}(k, \bar{a}, \bar{j}), J_{0,H}(k, \bar{a}, \bar{j}), \bar{a}, \bar{j} \in \mathcal{C}
\]

\[
\lim_{l \rightarrow \infty} J_{i,T}(k, \bar{a}, \bar{j}) = J^*_T(k, \bar{a}, \bar{j})
\]

\[
\lim_{l \rightarrow \infty} J_{i,H}(k, \bar{a}, \bar{j}) = J^*_H(k, \bar{a}, \bar{j})
\]

and

\[
\lim_{l \rightarrow \infty} J_i(k, \bar{a}, \bar{j}) = J^*(k, \bar{a}, \bar{j})
\]

(see [3, Proposition 2.1.2]).

APPENDIX B

PROOF OF LEMMA 1

**Proof:** Let states $(k, \bar{a}, \bar{j})$ and $(k, \bar{a}', \bar{j}_1)$ satisfy (5). If $zz \geq Z$, or if $k = K$ and $zz < Z$, then clearly $J^*(k, \bar{a}, \bar{j}) = J^*(k, \bar{a}', \bar{j}_1)$.

Thus, (6) follows. Now, let $k < K$ and $zz < Z$. Let $J_{0,T}(k, \bar{a}, \bar{j}) = J_{0,H}(k, \bar{a}, \bar{j}) = 0$ for all $0 \leq k \leq K - 1$. We prove that

\[
J_i(k, \bar{a}, \bar{j}) = J_i(k, \bar{a}', \bar{j}_1), \quad \forall l, k \in \{0, \ldots, K - 1\}, \quad zz < Z.
\]

(12)

Now, (6) follows after taking limits as $l$ goes to $\infty$ in (12).

To prove (12), it suffices to show the following for every $l$:

\[
J_i(k, \bar{a}, \bar{j}) = J_i(k, \bar{a}', \bar{j}_1)
\]

(13)

\[
J_{i,T}(k, \bar{a}, \bar{j}) = J_{i,T}(k, \bar{a}', \bar{j}_1).
\]

(14)

We prove (13) and (14) using induction. Now, (13) and (14) clearly hold for $l = 0$. We assume that (13) and (14) hold for every $l \leq L - 1$, and prove them for $l = L$. Let $C_u(\bar{a}, \bar{j}) = \{ \bar{j}': t_u, \bar{j} = u \}$ for $u \in \{0, \ldots, G - zz\}$. Thus, from (11)

\[
J_{i,H}(k, \bar{a}, \bar{j}) = \sum_{\bar{j} \in \mathcal{C}} B_{\bar{j}} J_{i-1}(k, \bar{a}, \bar{j}).
\]

\[
J_{i,T}(k, \bar{a}, \bar{j}) = \bar{V} + \sum_{\bar{j} \in \mathcal{C}} B_{\bar{j}} J_{i-1}(k + 1, \bar{a} \circ \bar{j}, \bar{j}_1) - J_{i,H}(k, \bar{a}, \bar{j}).
\]

Taking limits as $l$ goes to $\infty$, we get

\[
\lim_{l \rightarrow \infty} J_{i,T}(k, \bar{a}, \bar{j}) = \bar{V} + \sum_{\bar{j} \in \mathcal{C}} B_{\bar{j}} J_{i-1}(k + 1, \bar{a} \circ \bar{j}, \bar{j}_1) - \sum_{\bar{j} \in \mathcal{C}} B_{\bar{j}} J_{i}(k, \bar{a}, \bar{j}).
\]

\[
J_{i,H}(k, \bar{a}, \bar{j}) = \bar{X} + \sum_{\bar{j} \in \mathcal{C}} B_{\bar{j}} J_{i-1}(k, \bar{a}, \bar{j}).
\]

Now

\[
\sum_{\bar{j} \in \mathcal{C}} B_{\bar{j}} J_{i}(k, \bar{a}, \bar{j}) = \sum_{\bar{j} \in \mathcal{C}} B_{\bar{j}} J_{i}(k, \bar{a}, \bar{j})
\]

for every $u \in \{0, \ldots, G - zz\}$ whenever the receiver readiness states are i.i.d. and (5) holds. Thus, $J_{i,H}(k, \bar{a}, \bar{j}) = J_{i,H}(k, \bar{a}', \bar{j}_1)$. Hence, by induction, (13) follows. Equation (14) follows from similar arguments.

Henceforth, we denote the system state as $(k, z, t)$. Now, the Bellman’s equations are as follows for $k \leq K - 1$, $z < Z$, and $t \leq G - z$

\[
J^*(k, z, t) = \min \{ J^*_T(k, z, t), J^*_H(k, z, t) \}
\]

\[
J^*_T(k, z, t) = \bar{V} + \sum_{z, t = 0}^{z, t = 0} P_{0,\bar{C}}(z + t) J^*(k + 1, z + t, \bar{t})
\]

\[
J^*_H(k, z, t) = \bar{X} + \sum_{z, t = 0}^{z, t = 0} P_{0,\bar{C}}(z) J^*(k, z, \bar{t}).
\]

(15)

(16)

(17)

If $z \geq Z$, then as before $J^*(k, z, t) = 0$ for every $k \leq K$. Also, $J^*(k, z, t) = \infty$ if $z < Z$. As described in the previous section, Bellman’s equations can be solved using value iteration method. Let $J_i(k, z, t), J_{i,T}(k, z, t), J_{i,H}(k, z, t)$ be defined iteratively as follows for $0 \leq k \leq K - 1, 0 \leq z < Z$, and $0 \leq t \leq G - z$

\[
J_i(k, z, t) = \min \{ J_{i,T}(k, z, t), J_{i,H}(k, z, t) \}
\]

\[
J_{i,T}(k, z, t) = \bar{V} + \sum_{z, t = 0}^{z, t = 0} P_{0,\bar{C}}(z + t) J_{i-1}(k + 1, z + t, \bar{t})
\]

\[
J_{i,H}(k, z, t) = \bar{X} + \sum_{z, t = 0}^{z, t = 0} P_{0,\bar{C}}(z) J_{i-1}(k, z, \bar{t}).
\]

(18)

(19)

(20)

Also, $J_i(k, z, t) = 0$ if $z \geq Z$ and $J_i(k, z, t) = \infty$ if $z < Z$ for every $l$.

APPENDIX C

PROOF OF THEOREM 1

We prove a supporting lemma (Lemma 2) which shows that $\mathcal{P}(K, G, Z, t)$ can be solved using a linear program LP2 which we describe next. Subsequently, we use Lemma 2 to prove Theorem 1.

**LP2:** Maximize $\sum_{k=0}^{G-1} \sum_{z=0}^{G-1} \sum_{t=0}^{G-1} \sum_{k'=0}^{G-1} \sum_{t'=0}^{G-1} B_{k', t', z} J(k, z, t)$

Subject to:

1. $J(k, z, t) = 0$ for every $z \geq Z, k \leq K - 1, \text{ and } t \leq G - z$
2. $J(k, G - 1, z, t) = \bar{V} + h_{\bar{C}}(z)$ for every $z < Z$
3. $J(k, z, t) \leq J_H(k, z, t), k \leq K - 1,$
4) \[ \hat{\mathcal{J}}_k(k+z,t) = \mathcal{I} + \sum_{t=0}^{G_z} P_{k,t}(z) \hat{J}_k(k+z,t) \text{ for } k \leq K-1, \]
\[ z \geq Z-1, \text{ and } \mathcal{I} \leq G - z. \]
5) \[ \hat{\mathcal{J}}(k+z,t) \leq \hat{F}_k(k+z,t), \text{ for } k \leq K-1, \]
6) \[ \hat{\mathcal{J}}_y(k+z,t) = \mathcal{I} + \sum_{t=0}^{G_z} P_{k,t}(z) \hat{J}_k(k+1,z+t,t) \text{ for } k \leq K-1, \]
\[ z \geq Z-1, \text{ and } t \geq G - z. \]

Let \( \hat{J}_y^*(k,z,t) \), \( \hat{J}_y^*(k,z,t) \), and \( \hat{J}_y^*(k,z,t) \) denote the optimal solution of \( LP_2 \) for every \( k \leq K-1, \) \( z \in \{0, \ldots, G\} \), and \( t \in \{0, \ldots, G - z\} \).

**Lemma 2:** Let \( \beta_{k,z,t} \geq 0 \) for every \( (k,z,t) \). Then, the following hold.

(A1) The linear program \( LP_2 \) is always feasible.

(A2) If \( \hat{J}_y(k, z, t) \) is a feasible solution of \( LP_2 \), then \( J^*(k, z, t) \geq \hat{J}_y(k, z, t) \) for every \( (k, z, t) \).

(A3) If \( \beta_{k,z,t} > 0 \), then \( \hat{J}_y^*(k, z, t) = J^*(k, z, t) \).

**Proof:** Note that the assignment \( \hat{J}_y(K-1, z, t) = \mathcal{I} + \sum_{t=0}^{G_z} P_{k,t}(z) \hat{J}_k(k+1, z+t, t) \) for every \( z \geq Z, \) and \( J(k, z, t) = 0 \) otherwise, is a feasible solution of \( LP_2 \). Thus, (A1) follows. The proof for (A2) follows using arguments similar to those in [2, Ch. 7, pp. 376]. Next, \( J^*(k, z, t) \) is a feasible solution of \( LP_2 \). Thus, (A3) clearly follows from (A2).

Let \( J^*(k, z, t) \) denote the expected termination time from state \( (k, z, t) \) under policy \( \pi \). Also, let \( J_y^*(k, z, t) (J_y^*(k, z, t)) \) respectively the expected termination time if the sender transmits (backs off, respectively) in \( (k, z, t) \) and subsequent decisions are taken as per \( \pi \).

**Proof of Theorem 1:**

**Proof:** If \( z \geq Z \), then \( J^*(k, z, t) \) is 0 for any \( k, t \). Thus, (B1) in Fig. 5 obtains optimal termination times from every state \( (k, z, t) \) such that \( z \geq Z \). Thus, henceforth, we only consider \( z < Z \).

We prove the following using induction on \( k \).

**(H1)** For every \( (k, z, t), \) \( \hat{J}_y(k, z, t) = J^*(k, z, t) \) for \( k = K-1, \) (H1) follows from (1). Now, we assume (H1) for \( k > K-1 \) and prove (H1) for \( k = K-1 \).

In \( LP_2 \), we choose \( \beta_{k,z,t} = 1 \) if \( k = K-1 \) and 0 otherwise. Thus, \[ \hat{J}_y^*(k, z, t) = J^*(k, z, t) \] (from (A3) of Lemma 2).

Note that \( \hat{J}^*(k, z, t) \) is the optimal solution of \( LP_1 \) in Fig. 5 for \( k = K-1 \). Now, \( LP_1 \) in Fig. 5 for \( k = K-1 \) is similar to \( LP_2 \) except that it has fewer constraints, and the right-hand sides of these constraints have \( \hat{J}^*(k+1, z, t) \) instead of \( \hat{J}(k+1, z, t) \). By induction hypothesis, \( \hat{J}^*(k+1, z, t) = J^*(k+1, z, t) \). Thus, from (A2) of Lemma 2, the maximum value of the objective function of \( LP_1 \) is greater than or equal to that of \( LP_2 \). Thus, \[ \sum_{t=0}^{G_z} J^*(k, z, t) \geq \hat{J}_y^*(k, z, t) \] (from (A2) of Lemma 2).

It can be easily seen that \( J^*(k, z, t) \) for \( k > K-1 \) is feasible for \( LP_2 \). Thus, \[ J^*(k, z, t) \leq J^*(k, z, t) \] (from (A2) of Lemma 2).

Thus, from (21)–(23), \( \hat{J}^*(k, z, t) = J^*(k, z, t) \). Now, from (21), (H1) holds for \( k = K-1 \).

The optimality of \( \pi(K, Z) \) follows from (B3) and (H1).

**APPENDIX D**

**PROOFS OF THEOREMS 2 AND 3**

First, we derive some properties of the optimal solution (Lemmas 3 to 7) and using these we prove Theorems 2 and 3. For any policy \( \pi \)

\[ J_y^*(k, z, u) = \mathcal{I}, \text{ if } u \geq Z - z. \]

Let \( \pi^* \) be the optimal policy.

**Lemma 3:** Let \( z < Z, k < K \). Then, \( T_{k,z} \) is unique. If \( u \geq Z - z, \) \( u \in T_{k,z} \).

**Proof:** Uniqueness of \( T_{k,z} \) follows since Bellman’s equations (15)–(17) have unique solutions. Now, let \( u \geq Z - z \). Since \( z < Z, k < K \), at least one more transmission is required to reach a termination state. Hence, \( J_y^*(k, z, t) \geq \mathcal{I} \) for every \( t \). Thus, from (17)

\[ J_y^*(k, z, u) \geq \mathcal{I} + \sum_{t=0}^{G_z} P_{k,t}(z) \mathcal{I} \]

\[ = \mathcal{I} + J_y^*(k, z, u) \] (by (24)).

Thus, \( J_y^*(k, z, u) > J_y^*(k, z, u) \). Hence, \( u \in T_{k,z} \) by (15).

Thus, when \( z < Z \) and \( k < K, \) \( m_{k,z} \) is well defined.

**Corollary 1:** For \( z < Z, T_{k-1,z} = \{Z, \ldots, G-z\} \). Let \( u \leq Z - z \) and \( z < Z \). Now, from (16) and (17), \( J_y^*(k, z, t) \) is \( \mathcal{I} \) for every \( t \), \( J_y^*(K-1, z, u) = \mathcal{I} \). Thus, clearly, \( J_y^*(k-1, z, u) \leq J_y^*(k, z, u) \). Thus, from (8), \( u \geq T_{k-1,z} \).

The result follows from Lemma 3.

**Lemma 4:** For every \( k \leq K-1, z, t \leq G - z, \) \( J^*(k, z, t) \leq J^*(k+1, z, t) \)

**Proof:** If \( z \geq Z \), then \( J^*(k, z, t) = J^*(k+1, z, t) = 0 \). Thus, the lemma follows. Let \( z < Z \) and \( J_0(k, z, t) = 0 \) for every \( k \leq K-1, z < Z, t \leq G - z \). We show that for every \( l \)

\[ J_l(k, z, t) \leq J_l(k+1, z, t), \text{ for all } k, z, t. \]

Thus, the lemma follows after taking limits as \( l \) goes to \( \infty \) in (26).

Since \( J_l(k, z, t) = \infty \) if \( z < Z \) for every \( l \), \( 26 \) holds for \( l = 0 \). We assume that \( 26 \) holds for every \( l < L \), and prove (26) for \( l = L \).

By induction hypothesis and (19)

\[ J_{z,t}(k+1, z, t) \geq \mathcal{I} + \sum_{t=0}^{G_z} P_{k,t}(z) J_{z,t-1}(k+1, z+t, t_1) \]

\[ = J_{z,t}(k, z, t) \] (from (19)).

\[ J_{z,t}(k+1, z, t) \geq \mathcal{I} + \sum_{t=0}^{G_z} P_{k,t}(z) J_{z,t-1}(k, z, t_1) \]

(by induction hypothesis and (20))

\[ = J_{z,t}(k, z, t) \] (from (20)).

\[ J_{z,t}(k+1, z, t) \geq \min \{J_{z,t}(k, z, t), J_{z,t}(k, z, t)\} \]

(from (18), (27) and (28)).

\[ = J_{z,t}(k, z, t) \] (from (18)).

**Lemma 5:** Let \( k < K \) and \( z < Z \). Then, \( m_{k,z} > 0 \).
Proof: From (16) and since $\overline{V} \geq \overline{X}$

$$J^*_T(k, z, 0) \geq \overline{X} + \sum_{t=0}^{m_{k,z}} P_{0, t}(z) J^*_T(k+1, z, t)$$

$$\geq \overline{X} + \sum_{t=0}^{m_{k,z}} P_{0, t}(z) J^*_T(k, z, t) \text{ (by Lemma 4)}$$

$$= J^*_T(k, z, 0) \text{ (from (17)).}$$

Thus, from (8), $0 \not\in T_{k,z}$, for all $k, z$. The result follows.

Let $\mathcal{S}_{k,z} = \{ u : P_{0, u}(z) > 0 \}$ if $k > 0$ and $\mathcal{S}_{k,z} = \{ 0, \ldots, G \}$.

**Lemma 6:** For any policy $\pi$, if $J^*(k+1, z, u) = J^*(k+1, \overline{\pi}, u)$ for every $z$ and $u \in \mathcal{S}_{k+1, z}$, then for every $z < Z$ and $t \leq G - z$,

$$J^*_T(k, z, t) = J^*_T(k, z, t).$$

**Proof:** Note that

$$J^*_T(k, z, t) = \overline{V} + \sum_{u=0}^{m_{k,z}} P_{0, u}(z + t) J^*_T(k+1, z + t, u).$$

Thus, the result follows from the condition given in the lemma and (16).

Now we define some additional notations. Let $\mathcal{A}(z) = \{ 0, \ldots, G - z \}$. Note that $\mathcal{A}(z)$ is the state space of aggregate readiness process of $G - z$ receivers. Consider a set $A \subseteq \mathcal{A}(z)$. Let $r_{v, u}(A)$ denote the probability that the first state visited in $A$ is $u$ starting from state $v$ in the aggregate readiness process of $G - z$ receivers. Also, let $x_v(A)$ denote the product of $\overline{X}$ and the expected number of sample points required to reach any of the states $u \in A$ for the first time starting from state $v$ in the aggregate readiness process of $G - z$ receivers.

Any policy needs to transmit at least once more from a state $(k, z, t)$ for $k < K, z < Z$. Hence, if $k < K, z < Z$

$$J^*(k, z, t) = \min_{A \subseteq \mathcal{A}(z)} \left\{ x_v(A) + \sum_{u \in A} r_{v, u}(A) J^*_T(k, z, u) \right\} \quad (29)$$

$$= x_v(T_{k,z}) + \sum_{u \in T_{k,z}} r_{v, u}(T_{k,z}) J^*_T(k, z, u). \quad (30)$$

**Lemma 7:** Let the aggregate readiness process of the unsatisfied receivers be a BD process and $z < Z, k < K, t \leq m_{k,z}$

$$J^{\alpha}(k, z, t) = s_{k,m_{k,z}}(z) + J^*_T(k, z, m_{k,z})$$

$$= \min_{u \geq 0} \left\{ s_{k,u}(z) + J^*_T(k, z, u) \right\}. \quad (31)$$

**Proof:** Since the aggregate readiness process of unsatisfied receivers is BD and $t \leq m_{k,z}$,

$$x_v(T_{k,z}) = s_{k,m_{k,z}}(z) \quad \text{and}$$

$$r_{v, u}(T_{k,z}) = 1, \quad \text{for} \quad u = m_{k,z}$$

$$= 0, \quad \text{o.w.}$$

Now, (31) follows from (30).

From (31), since $m_{k,z} \geq t$

$$J^{\alpha}(k, z, t) \geq \min_{u \geq 0} \left\{ s_{k,u}(z) + J^*_T(k, z, u) \right\}. \quad (32)$$

From (29)

$$J^{\alpha}(k, z, t) \leq \min_{u \geq t} \left\{ s_{k,u}(z) + J^*_T(k, z, u) \right\}. \quad (33)$$

Thus, (32) follows.

**Corollary 2:** Let the aggregate readiness process of the unsatisfied receivers be a BD process. Then, if $0 < k < K, z < Z$, and $t \in \mathcal{S}_{k,z}$

$$J^{\alpha}(k, z, t) = s_{k,m_{k,z}}(z) + J^*_T(k, z, m_{k,z})$$

$$= \min_{u \geq t} \left\{ s_{k,u}(z) + J^*_T(k, z, u) \right\}. \quad (34)$$

**Proof:** Since the aggregate readiness process of unsatisfied receivers is a BD process, $\mathcal{S}_{k,z} = \{ 0, 1 \}$ for every $k > 0$ and $z < Z$. Thus, by Lemma 5, $t \leq m_{k,z}$. Thus, (33) follows from Lemma 7. Using similar arguments as in the proof of (32) from (31), it can be shown that (34) follows from (33).

**Proof of Theorem 2:**

**Proof:** Let $\widehat{J}(k, z, t)$ be as defined in Fig. 7. We show that for every $k \leq K - 1, z, u \in \mathcal{S}_{k,z}$

$$\widehat{J}(k, z, t) = J^{\ast}(k, z, t) \quad (35)$$

Let $z \geq Z$. Clearly, $J^*(k, z, t) = J^*(k, z, t) = 0$, for every $\pi$. Thus, (35) follows from (C1) in Fig. 7. Thus, henceforth, we consider the case $z < Z$. Also, when $K = 1$, clearly $\pi( K, z)$ is optimal. Thus, henceforth, we consider the case $K > 1$.

By (C1) and (C2) in Fig. 7, $\widehat{J}(K-1, z, t) = J^{\ast}(K-1, z, t)$. Now, from Corollary 1, $m_{K-1,z} = Z$. Moreover, for $k > 0$, since the aggregate readiness process is a BD process. Hence, for any $t \in \mathcal{S}_{k-1,z}, t \leq Z - z$. Thus, $\pi^\ast$ will transmit when $Z - z$ unsatisfied receivers are ready. From (C2) in Fig. 7, $\pi( K, z)$ also transmits only when $Z - z$ unsatisfied receivers are ready. Thus, (35) holds.

We assume that (35) holds for all $\hat{K} \in \{ K - 1, \ldots, k + 1 \}$, and prove (35) for $k$. First, for any policy $\pi$ and $z < Z$

$$J^{\alpha}(k, z, t) = \overline{V} + (1 - \alpha_0(z)) J^*(k + 1, z + t, 1)$$

$$+ \alpha_0(z) J^*(k + 1, z + t, 0). \quad (36)$$

We first consider $k \geq 1$. From (C0) in Fig. 7, (36), Lemma 6, and the induction hypothesis, for every $u$

$$\widehat{J}(k, u, u) = J^{\ast}(k, u, u) = J^{\ast}(k, u, u). \quad (37)$$

Now, $J^{\ast}(k, z, t) = s_{k, \tau(k,z)}(z) + J^{\ast}(k, z, \tau(k,z)). \quad (38)$

Thus, from (C4), (C5), (37), and (38), for every $t \in \mathcal{S}_{k,z}$

$$\widehat{J}(k, z, t) = J^{\ast}(k, z, t). \quad (39)$$

From (29)
Now, for every $t \in \mathcal{S}_k$,
\[
J_{\tau_1(nK, n)}(k, z, t) = \begin{cases} 
  s_{\tau_1(nK, n)}(z) + J_T^n(k, z, \tau(z, k, z)) & (\text{from (37) and (38)}) \\
  s_{\tau_1}(z) + \min_{k \leq \tau(z, k, z)} \left\{ s_{\tau_1}(z) + J_T^n(k, z, \tau(z, k, z)) \right\} & (\text{by Corollary 2}) \\
\end{cases}
\]
(46)

Thus, from (39) and (44), (35) hold for $k \geq 1$.

Now, we prove (35) for $k = 0$. Thus, from (C0) in Fig. 7, (36), Lemma 6, and the induction hypothesis, for every $u$
\[
J_T^n(0, 0, u) = J_T^n(0, 0, u) = J_T^n(0, 0, u).
\]
(45)

We consider two cases. First, $m_{0,0} \geq t$ or $t \in \mathcal{T}_{0,0}$. Second, $m_{0,0} < t$ and $t \notin \mathcal{T}_{0,0}$. In the first case, similar to the proof in Lemma 7, it can be shown that
\[
J_T^n(0, 0, t) = \min_{u \geq 1} \left\{ s_{\tau_1}(z) + J_T^n(0, 0, u) \right\}
\]
(47)

From (29), $J_T^n(0, 0, t) \leq J_{2,0}(0, 0, t)$. Thus,
\[
J_T^n(0, 0, t) = J_{2,0}(0, 0, t).
\]
(47)

If case 1 holds, then by (46) and (29), $J_{1,0}(0, 0, t) \leq J_{2,0}(0, 0, t)$.

If case 2 holds, from (47) and (29), $J_{1,0}(0, 0, t) \geq J_{2,0}(0, 0, t)$. Thus,
\[
J_T^n(0, 0, t) = \min_{u \geq 1} \left\{ J_{1,0}(0, 0, t), J_{2,0}(0, 0, t) \right\} \text{ for every } t.
\]
Thus, (35) follows from (45), (C6) and (C7) in Fig. 7. The result follows.

Proof for Theorem 3:

Proof: We first show that the optimal policy is threshold type, i.e., if $t \in \mathcal{T}_{k,i}, \text{then } u \in \mathcal{T}_{k,i}$, for every $u \geq t$. Let $J_{0,T}(k, z, t) = J_{0,H}(k, z, t) = 0$ if $k < K$. We prove that for each iteration $l$, for every $k \leq K - 1$, $z < Z$, and $t \leq G - z$

\[
J_{0,T}(k, z, t) < J_{1,H}(k, z, t), \text{ then } J_{1,T}(k, z, t + 1) < J_{1,H}(k, z, t + 1)
\]
(H1)

\[
J_l(k, z + 1, t) \leq J_l(k, z, t), \text{ and}
\]
(H2)

\[
J_l(k, z + 1, t - 1) \leq J_l(k, z, t).
\]
(H3)

Clearly, (H1), (H2), and (H3) hold for $l = 0$. We assume that (H1), (H2), and (H3) hold till the $l$th iteration, and prove these in the $l + 1$th iteration.

Let $p_i(z)$ be the probability that $i$ out of $G - z$ unsatisfied receivers are ready. Then
\[
J_{l+1,H}(k, z, t) = \sum_{i=0}^{G-z} p_i(z) J_l(k, z, i) \text{ (by (20))}
\]
(48)

Now, from (19)
\[
J_{l+1,T}(k, z, t + 1)
\]
\[
= \sum_{i=0}^{G-z-1} p_i(z + t + 1) J_l(k + 1, z + t + 1, i).
\]
(49)

Now, from (49), (51), and (52)
\[
J_{l+1,T}(k, z, t + 1)
\]
\[
= \sum_{i=0}^{G-z-1} p_i(z + t + 1) J_l(k + 1, z + t + 1, i)
\]
\[
\times (k + 1, z + t + 1, i)
\]
\[
+ \sum_{i=0}^{G-z-1} p_i(z + t + 1)(1 - p) J_l(k + 1, z + t, i)
\]
(51)

By induction hypotheses (H2) and (H3) and since $0 \leq p \leq 1$
\[
J_l(k + 1, z + t + 1, i)
\]
\[
\leq p J_l(k + 1, z + t + 1, i + 1) + (1 - p) J_l(k + 1, z + t, i).
\]
(52)

Similarly, it can be shown that
\[
J_{l+1,H}(k, z, t + 1) \leq J_{l+1,H}(k, z, t).
\]
(54)

Proof of statement (H1): Let $J_{l+1,T}(k, z, t) < J_{l+1,H}(k, z, t)$.

Then, from (53)
\[
J_{l+1,T}(k, z, t + 1) < J_{l+1,H}(k, z, t)
\]
\[
= J_{l+1,H}(k, z, t + 1) \text{ (by (48)).}
\]
(53)

Thus, (H1) holds for iteration $l + 1$. 

Proof of statement (H2): From (50)
\[ J_{i+1,T}(k, z + 1, t) = J_{i+1,T}(k, z, t + 1). \] (55)
Thus, from (53), \( J_{i+1,T}(k, z + 1, t) \leq J_{i+1,T}(k, z, t) \). Then, (H2) follows from (18) and (54).

Proof of statement (H3): From (48) and (54)
\[ J_{i+1,H}(k, z + 1, t - 1) \leq J_{i+1,H}(k, z, t). \]
From (55)
\[ J_{i+1,T}(k, z + 1, t - 1) \leq J_{i+1,T}(k, z, t). \]
Then, (H3) follows from (18).

Thus, (H1), (H2), and (H3) hold for all \( l \).

After taking limits as \( l \) goes to \( \infty \) in (H1), it follows that the optimal policy is threshold type.

Now, we show that the algorithm in Fig. 10 obtains a threshold that minimizes the expected termination time for every \( k \leq K \) and \( z < Z \).

Let \( G^*(k, z) \) denote the expected time to terminate under a policy \( \pi \) after the \( k \)th transmission and the subsequent backoff, if \( z \) receivers are satisfied after \( k \) transmissions.

We show that for every \( k \leq K - 1 \) and \( z \)
\[ G^*(k, z) = G^{*2}(k, z). \] (56)
Since \( G^*(k, z) = \tau^{2}(K, z) \), (56) proves the optimality of \( \tau^{2}(K, Z) \).

Note that if \( z \geq Z \), then \( G^*(k, z) = G^{*2}(k, z) = 0 \) for every \( k \).

Thus, (56) follows. Henceforth, we consider \( z < Z \).

Let \( k = K - 1 \). Clearly, \( \pi \) transmits when at least \( Z - z \) unsatisfied receivers are ready. Thus, \( G^{*}(K - 1, z) = \frac{1}{\pi_{z-}} \sum_{z} \hat{\nu} \) where \( \{ \hat{\nu} \} \) are as defined in Fig. 10. Thus, (56) follows.

Now, we assume (56) for every \( \hat{k} > k \) and show (56) for \( k \) clearly
\[ G^{*}(k, z) = \frac{1}{\hat{\nu}_{m_{h_{z}}}} + \frac{1}{\hat{\nu}_{m_{h_{z}}}} \sum_{z \geq m_{h_{z}}} q_{m_{h_{z}}, v}(z + v)G^{*}(k + 1, z + v) \] (57)
where \( \{ q_{m_{h_{z}}, v} \} \) are as defined in Fig. 10. Now, from Lemmas 3 and 5, \( 0 < m_{h_{z}} \leq Z - z \). Thus, from (57)
\[ G^{*}(k, z) \geq \min_{1 \leq \hat{k} \leq K} \left\{ \frac{1}{\hat{\nu}_{v}} + \frac{1}{\hat{\nu}_{v}} \sum_{z \geq m_{h_{z}}} q_{m_{h_{z}}, v}(z + v)G^{*}(k + 1, z + v) \right\} \] (from induction hypothesis). (58)

Clearly
\[ G^{*2}(k, z) \leq G^{*2}(K, z) = G^{*}(k, z). \]
Thus, \( G^{*2}(k, z) \geq G^{*}(k, z) \). The result follows.

I. INTRODUCTION

Let \( A \) be a matrix with complex entries and \( A^* \) denote the conjugate transpose of \( A \). Let \( || \cdot || \) denote the Frobenius norm of a matrix, i.e.,
\[ ||A|| = \sqrt{\text{tr}(A^*A)}. \]

A square matrix \( A \) is called unitary if \( A^*A = AA^* = I \), where \( I \) denotes the identity matrix. We denote by \( U(n) \) the set of all \( n \times n \) unitary matrices.

REFERENCES
