# Optical Bandgap and Photoconductance of Electrospun Tin Oxide Nanofibers

## Abstract

Optical and photoconductive properties of transparent SnO<sub>2</sub> nanofibers, made from C<sub>22</sub>H<sub>44</sub>O<sub>4</sub>Sn via electrospinning and metallorganic decomposition, were investigated using Fourier transform infrared and ultraviolet (UV)/visible spectrometry and the two-probe method. Their optical bandgap was determined from their UV absorption edge to be 3.95–4.08 eV. Their conductance responds strongly to UV light for a wavelength of 254 nm: in air its steady-state on-to-off ratios are 1.31–1.56 (rise) and 1.25–1.33 (fall); its 90% rise and fall times are 76–96 and 71–111 s, respectively. In a vacuum of about 10<sup>-4</sup> torr, its on-to-off ratios are higher than 35.6 (rise) and 3.4 (fall), respectively, and its 90% rise and fall times are longer than 3×10<sup>4</sup> s.

### INTRODUCTION

Transparent conductive oxides (TCOs) have received extensive attention because of their important optoelectronic applications such as electrochromic devices, transparent electrodes, and antireflection coatings in solar cells.<sup>1</sup> Tin oxide or stannic oxide (SnO<sub>2</sub>) is a typical TCO with a tetragonal rutile structure and a bandgap ( $E_g$ ) of around 3.6 eV, which makes it transparent to light up to the ultraviolet (UV).<sup>2</sup> It is also chemically inert, mechanically hard, and thermally heat resistant and has seen additional applications as sensors, heat mirrors, and heterogeneous catalysts.<sup>3</sup> Its conductivity can be changed drastically either by extrinsic impurity doping or by intrinsic formation of oxygen vacancies in its lattice, which donate electrons.<sup>2,3</sup> Since film is the preferred morphology for most optoelectronic, sensing, and heat reflecting applications, SnO<sub>2</sub> films have been synthesized by numerous methods,<sup>1–3</sup> such as chemical vapor deposition,<sup>4</sup> sol-gel,<sup>5</sup> spray pyrolysis,<sup>6</sup> and polymeric precursor,<sup>7</sup> and their electrical and optical properties have been well characterized.<sup>1–7</sup> However, for many applications such as the line light source or dielectric waveguide, the fiber morphology is more favorable. Unfortunately, so far only a few ways, such as thermal decomposition,<sup>8</sup> template and oxidization,<sup>9</sup> laser ablation or vapor-liquid-solid growth,<sup>10</sup> vapor deposition,<sup>11,12</sup> and electrospinning,<sup>13–15</sup> have been developed to fabricate SnO<sub>2</sub> nanofibers or ribbons. Their optical and optoelectronic properties have been only barely touched<sup>10–13</sup> even though such property characterization is indispensable for their optoelectronic applications. For ex-

ample, only Liu *et al.*,<sup>10</sup> Lee *et al.*,<sup>11</sup> and Mathur *et al.*<sup>12</sup> have evaluated the photoconductance of SnO<sub>2</sub> nanowires and only Lee *et al.* have presented their UV photoresponse.<sup>11</sup> To our knowledge, no report has been made neither on the optical bandgap ( $E_o$ ) of SnO<sub>2</sub> nanowires, an important parameter for their optoelectronic applications in general, nor on the photoconductance of electrospun SnO<sub>2</sub> nanofibers. We have developed two recipes for electrospinning SnO<sub>2</sub> fibers,<sup>14–16</sup> characterized their electrical properties,<sup>17</sup> and applied a single electrospun SnO<sub>2</sub> fiber in gas detection.<sup>18</sup> This letter investigates their optical and photoconductive properties, with its emphasis on the determination of their optical bandgap and evaluation of their conductive response to UV light.

### EXPERIMENT

The synthetic procedure and characterization methods for SnO<sub>2</sub> fibers have been reported in details.<sup>15,16</sup> Briefly, precursor fibers and mats were electrospun from a solution of commercial poly(ethylene oxide) (molecular weight of 900 000), chloroform, and dimethyldiiododecanoate tin (C<sub>22</sub>H<sub>44</sub>O<sub>4</sub>Sn) using a homemade electrospinning setup<sup>15</sup> onto quartz plates, for subsequent spectral characterization, and (111)-oriented single crystal silicon wafers with their surface thermally oxidized and patterned with gold contacts, for subsequent conductive measurement. The as-deposited precursor fibers and mats were subsequently thermally decomposed in air for 2 h at 100, 200, 300, 400, 500, and 600 °C, respectively. Our previous x-ray diffraction, Raman microspectrometry, and Fourier transform infrared (FTIR) spectrometry characterization indicated that the fibers are rutile-structured SnO<sub>2</sub> after thermal decomposition at and

above 400 °C.<sup>15,16</sup> Optical properties of mats decomposed at different temperatures were measured using a Perkin-Elmer Spectrum One FTIR spectrometer and a Perkin-Elmer Lambda 35 ultraviolet/visible (UV/VIS) spectrometer. Mat samples were directly used for the UV/VIS analysis. For the FTIR analysis, mats were mechanically stripped off their substrate as powder which was sampled using the Nujol-mulling technique.<sup>16</sup> Electrical measurement was conducted on a single fiber decomposed at 600 °C using the two-probe method in air and in a vacuum about  $10^{-4}$  torr. The UV light source is a Minerallight UVGL-25 lamp with its maximum output power density of  $460 \mu\text{W}/\text{cm}^2$  at the wavelength ( $\lambda$ ) of 254 nm.

## RESULTS AND DISCUSSIONS

FTIR spectra [Fig. 1(a)] reveal that organic groups in precursor fibers decompose mostly between 200 and 300 °C and the fibers transform into incipient polycrystalline rutile structure at around 400 °C.<sup>16</sup> The synthesized fibers demonstrate a strong absorption band around  $600 \text{ cm}^{-1}$ , characteristic of the stretching Sn–O vibration of transverse  $E_u$  mode in the rutile-structured  $\text{SnO}_2$ .<sup>19,20</sup> On the other hand, the fibers are transparent from near IR ( $\lambda=1100 \text{ nm}$ ) to their UV absorption edge. The edge shifts toward the longer wavelength when the thermal decomposition temperature (TDT) increases from 100 to 300 °C, above which further shift is not evident [Fig. 1(b)].

It is well accepted that the bandgap is direct in the rutile-structured  $\text{SnO}_2$ .<sup>1–3</sup> During its direct interband transition, the optical absorption coefficient  $\alpha$  follows as a function of incident photon energy ( $E$ ) on the long-wavelength (low  $E$ ) side,

$$\alpha = [A(E - E_o)]^{1/2}, \quad (1a)$$

or

$$\alpha^2 = A(E - E_o), \quad (1b)$$

where  $E_o$  is the optical bandgap and  $A$  is a constant.<sup>21</sup> Since  $\alpha$  and transmittance ( $T$ ) are correlated as

$$T = e^{-\alpha L}, \quad (2a)$$

or

$$\alpha = -(\ln T)/L, \quad (2b)$$

where  $L$  is the thickness of the sample, we have

TABLE I. Optical bandgap determined from UV absorption edge.

TDT (°C)	300	400	500	600
$E_o$ (eV) <sup>a</sup>	$3.985 \pm 0.004$	$3.997 \pm 0.001$	$3.952 \pm 0.002$	$4.087 \pm 0.002$

<sup>a</sup>The errors given in this report are fitting errors.

$$(\ln T)^2 = AL^2(E - E_o), \quad (3)$$

which predicts a linear relation between  $(\ln T)^2$  and  $E$ . Such a linear relation is confirmed in the photon energy range of 4.3–5.2 eV (Fig. 2), and its extrapolation to the  $E$ -axis gives us  $E_o$  values for different TDTs (Table I). Overall, the  $E_o$  value increases with heat treatment temperature (HTT) but the variation is very small. The values lie within the reported range of 3.8–4.2 eV for  $\text{SnO}_2$  thin film determined in the same way<sup>5–7</sup> and are higher than  $E_g \approx 3.6 \text{ eV}$ . The difference may be attributed to the Burnstein-Moss effect<sup>22,23</sup> (due to the filling of the conduction band by free carriers<sup>24</sup>), the two-dimensional quantum confinement (quantum wire) effect caused by the porosity,<sup>25</sup> as well as the defect effect.<sup>5</sup> In literature (Ref. 26, for example),  $\alpha^i$  ( $i=1/2, 1$ ) and  $(\alpha E)^j$  ( $j=1/2, 1$ , and 2) against  $E$  have also been linearly fitted and extrapolated to determine  $E_o$  values. Such processing sometimes results in approximately the same  $E_o$  values as listed in Table I or values closer to the  $E_g$  value. However, they are based on assumptions that cannot be justified for rutile-structured  $\text{SnO}_2$  (for example, an indirect bandgap) (Ref. 27) and are not adopted here.

The fiber's conductance ( $G$ ) is insensitive to visible light, which is consistent with its transparency to visible light [Fig. 1(b)]. However,  $G$  is sensitive to UV light of 254 nm wavelength (Figs. 3 and 4). Upon the UV illumination in air,  $G$  increases sharply and then asymptotically to its steady value with the on-to-off ratio ( $\xi$ ) of 1.58 (first cycle) and 1.31 (second cycle); when the UV light is turned off,  $G$  decreases asymptotically to its new steady values with  $\xi = 1.33$  (first cycle) and 1.25 (second cycle). The 90% rise and fall times ( $t_r$  and  $t_f$ ) of the conductance are 111 and 96 s (first cycle) and 76 and 71 s (second cycle), respectively. It is also interesting that  $G$  changed by 19.6% after the first UV on-and-off cycle, implying an only partially irreversible change. However, its change is only 3.5% in the second cycle. In fact, the  $G$  change follows

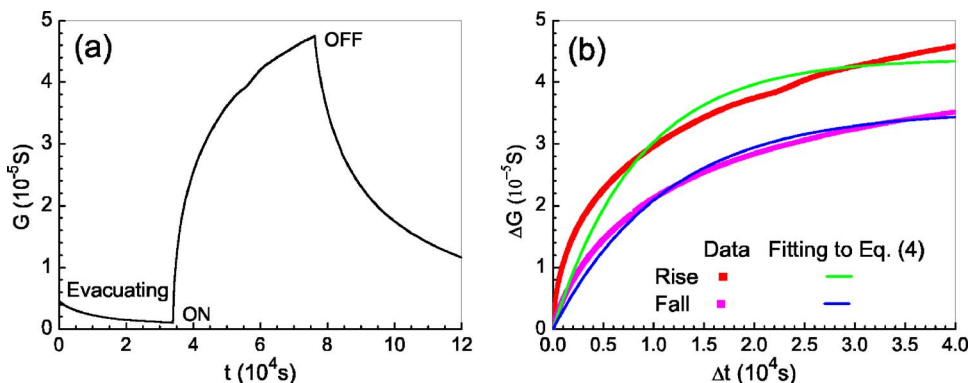

FIG. 4. (Color online) Transient UV responses in vacuum of  $\sim 10^{-4}$  torr: (a)  $G$  vs time and (b)  $\Delta\sigma$  vs  $\Delta t$ .

TABLE II. Main photoresponsive characteristics of the fiber.

Environment	Cycle	$\xi$	$t_r$ or $t_f$ (s)	$\Delta G_0$ ( $\mu\text{S}$ )	$\tau$ (s)
In air	First rise	1.56	$t_r=96$	$2.349\pm 0.009$	$36.1\pm 0.5$
	First fall	1.33	$t_f=111$	$1.533\pm 0.006$	$23.1\pm 0.5$
	Second rise	1.31	$t_r=76$	$1.543\pm 0.005$	$23.7\pm 0.4$
	Second fall	1.25	$t_f=71$	$1.304\pm 0.003$	$18.5\pm 0.3$
In vacuum	Rise	$>35.6$	$t_r>30432$	$4.384\pm 0.002$	$8522\pm 15$
	Fall	$>3.40$	$t_f>30910$	$3.536\pm 0.001$	$11227\pm 11$

$$\Delta G = \Delta G_0(1 - e^{-\Delta t/\tau}), \quad (4)$$

where  $\Delta t$  is the time measured from the UV-switching moment and  $\Delta G_0$  and  $\tau$  are listed in Table II. While  $\Delta G_0$  is proportional to  $\xi$ ,  $\tau$  is also a measure of response time, corresponding to  $\Delta G$  change by 63.8% and less than  $t_r$  and  $t_f$  (Table II). The wide optical bandgap and high photoconductivity imply promising optoelectronic applications of the nanofibers. It is noteworthy that the photoresponse times and gas-sensing response times<sup>18</sup> are close, both characteristic of the surface adsorption and desorption processes triggered by switching of either analyte or UV light.<sup>11,28,29</sup>

In air, the adsorption of oxygen on the SnO<sub>2</sub> surface can be depicted by the relation,

It consumes free electrons in SnO<sub>2</sub>, bends the conducting band immediately below the adsorbing surface and grain boundaries, and produces a depletion layer that resists electron transport. Since the incident UV light has a photon energy (4.89 eV) higher than  $E_o$ , it generates nonequilibrium electron-hole pairs. Some photogenerated holes ( $h^+$ ) further detach O<sub>2</sub><sup>-</sup> from the SnO<sub>2</sub> surface,

and reduce the thickness of the depletion region. Both mechanisms contribute to the observed increase of conductance, i.e., photoconductance. When the UV light is off, the reverse processes occur and  $G$  decreases.

Dark conductance in vacuum is less than that in air due to the evacuation of the reducing moisture from the chamber.  $G$  shows a stronger, though sluggish response to the UV light in vacuum. As soon as the UV light is turned on,  $G$  increases monotonously for 44 ks by a factor of 35.56 without stabilization. After the UV light is off,  $G$  decreases for 51 ks by a factor of 3.40 without stabilization, either [Fig. 4(a)]. Since  $G$  stabilization lasts longer than our measuring system (especially its vacuum pump) can work continuously,  $t_r$  and  $t_f$  cannot be evaluated as in air. However, they must be longer than the time it takes  $G$  to change 90% of the measured maximum  $\Delta G$  values, 30 432 s (rise) and 30 910 s (fall), which are in turn longer than  $t_r$  and  $t_f$  in air by two orders of magnitude (Table II). So far as the measured  $\Delta G$  is concerned, it also roughly follows Eq. (4), and its main characteristics are also listed in Table II. The photoresponse of our electrospun SnO<sub>2</sub> nanowires is similar to those of thermally evaporated SnO<sub>2</sub> nanowires.<sup>11</sup> Since the vacuum was only about 10<sup>-4</sup> torr, there still were oxygen molecules in the

chamber and therefore adsorbed O<sub>2</sub><sup>-</sup> species on the SnO<sub>2</sub> surface. The adsorption and desorption processes discussed in the previous paragraph still work, only with a lower partial pressure of oxygen ( $P_{\text{O}_2}$ ), a lower surface concentration of O<sub>2</sub><sup>-</sup> ([O<sub>2</sub><sup>-</sup>]), and accordingly, a thinner depletion layer than in air. The thinner depletion layer can be totally eliminated by the UV illumination and  $G$  will be increased more in vacuum than in air. Kinetically, however, the lower  $P_{\text{O}_2}$  and [O<sub>2</sub><sup>-</sup>] values slow down reactions (4) and (5) in vacuum, resulting in longer photoresponse times than in air.

## CONCLUSIONS

Optical and photoconductive properties of electrospun tin oxide nanofibers were investigated in UV, VIS, and IR ranges. It was found that the fibers are transparent from 1100 nm to their UV absorption edge. Their optical bandgap lies between 3.95 and 4.08 eV. In air, the conductance of a fiber heat treated at 600 °C responds sensitively to UV light of 254 nm wavelength (4.89 eV photon energy), with its steady on-to-off ratios 1.31–1.56 (rise) and 1.25–1.33 (fall) and its 90% rise and fall times between 76–96 and 71–111 s, respectively. The photoresponse in vacuum is stronger and slower, with the on-to-off ratios higher than 35.6 (rise) and 3.4(fall), respectively, and the 90% rise and fall response times longer than  $3 \times 10^4$  s.

## ACKNOWLEDGMENTS

The authors would like to thank Professor Jack Fischer, with the Laboratory for the Research on the Structure of Matter at the University of Pennsylvania, for his theoretical help.
