A Lower Bound Result for the Common Element Problem and Its Implication for Reflexive Reasoning

Abstract
In this paper we prove a lower bound of $\Omega(n \log n)$ for the common element problem on two sets of size $n$ each. Two interesting consequences of this lower bound are also discussed. In particular, we show that linear space neural network models that admit unbalanced rules cannot draw all inferences in time independent of the knowledge base size. We also show that the join operation in data base applications needs $\Omega(\log n)$ time given only $n$ processors.

A Lower Bound Result for the Common Element Problem and its Implication for Reflexive Reasoning

Paul Dietz ¹, Danny Krizanc², Sanguthevar Rajasekaran³, and Lokendra Shastri³

Abstract In this paper we prove a lower bound of $\Omega(n \log n)$ for the common element problem on two sets of size $n$ each. Two interesting consequences of this lower bound are also discussed. In particular, we show that linear space neural network models that admit unbalanced rules cannot draw all inferences in time independent of the knowledge base size. We also show that the join operation in data base applications needs $\Omega(\log n)$ time given only $n$ processors.

1 Introduction

In [Shastri & Ajjanagadde 1993] it is argued that there must exist a cognitively significant class of reasoning that can be processed using neural networks whose size is only linear in $|KB|$, the size of the knowledge-base, and in time that is only proportional to the length of the derivation and independent of $|KB|$. Reasoning that can be carried out within these space-time constraints has been referred to as reflexive reasoning [Shastri 1991].

The motivation for focusing on reflexive reasoning stems from cognitive as well as biological considerations. The linear space constraint arises from the relation between the expected size of a common sense KB and the number of neurons available for encoding such a KB. The time constraint is motivated by the observation that the speed at which we perform common sense reasoning (say, during language understanding) does not slow down as the size of the KB grows significantly.

A detailed characterization of reflexive reasoning requires an answer to the following question: ‘What are the formal constraints on the derivations computable by linear sized neural networks in time independent of the network size?’ A partial answer to this question was provided by SHRUTI – a neurally motivated model of reflexive reasoning described

¹Dept. of CS, Univ. of Rochester
²School of CS, Carleton Univ.
³Dept. of CIS, Univ. of Pennsylvania
⁴The label is intended to underscore the fact that such reasoning occurs spontaneously, effortlessly and without conscious effort — as it were a reflexive response of the cognitive agent.
in [Ajjanagadde & Shastri 1993]; [Shastri & Ajjanagadde 1993]; [Mani & Shastri 1992]. In particular, work on SHRUTI prompted the conjecture that when reasoning via backward chaining, any reflexive reasoning system must restrict itself to balanced rules (see Section 3.2) and lead to the identification of a class of queries that can be answered in a reflexive manner [Shastri 1993].

In this paper we prove a lower bound result for the common-element problem. This result establishes a lower bound of $\Omega(\log n)$ on the time required for deriving inferences involving unbalanced rules, and hence, provides a formal proof of the above conjecture. We also apply the lower bound to show that a similar result also holds for the JOIN operation in relational data bases.

Section 2 states and proves the lower bound result for the common-element problem. Section 3 provides a brief overview of SHRUTI and relate the lower bound result to the problem of reflexive reasoning with unbalanced rules. Section 4 relates the result to the JOIN operation.

2 The Lower Bound

The Common Element Problem (CEP): Given two sets $S_1$ and $S_2$ where $|S_1| = |S_2| = n$, decide if the two sets are disjoint.

Lemma 2.1 Any comparison based algorithm for CEP takes $\Omega(n \log n)$ time on the comparison tree model.

Proof. We'll reduce the problem of sorting to CEP.

Let $K = k_1, k_2, \ldots, k_n$ be any sequence of $n$ numbers that we want to sort. Let $X = x_1, x_2, \ldots, x_n$ be the sorted order of the sequence $K$. We construct an instance of CEP as follows: Take $S_1$ to be $\{(k_1, 0), (k_2, 0), \ldots, (k_n, 0)\}$ and $S_2$ to be $\{(k_1, 1), (k_2, 1), \ldots, (k_n, 1)\}$.

We'll show that any algorithm for CEP would have to compare $x_i$ with $x_{i+1}$, for each $i$, $1 \leq i \leq (n - 1)$. Realize that this will imply the stated lemma on the comparison tree model (since these comparisons will yield the sorted order and sorting takes $\Omega(n \log n)$ time in the worst case).

Our claim is that any algorithm for CEP on these two sets $S_1$ and $S_2$ should have decided the relative ordering between the elements $(x_i, 1)$ and $(x_{i+1}, 0)$ for each $i$, $1 \leq i \leq n$. If not, we could replace $(x_i, 1)$ in $S_2$ with $(x_{i+1}, 0)$ and force the algorithm to output an incorrect
answer. Realize that replacing \((x_i, 1)\) with \((x_{i+1}, 0)\) does not in any way affect the orderings imposed by other comparisons made by the algorithm. □

**Lemma 2.2** Any algorithm for CEP takes \(\Omega(n \log n)\) time even on the Random Access Machine model.

**Proof.** The above algorithm seems to account for only \(n\) comparisons (though among the right pairs). We now show that if \(T(n)\) is the run time of any algorithm for CEP on two sets of size \(n\) each, then we could sort any set of size \(n\) in time \(O(n + T(n))\). We’ll make use of the fact that the algorithm for CEP should have decided the relative ordering between \(x_i\) and \(x_{i+1}\), for each \(i\), \(1 \leq i \leq n\).

Construct a graph \(G(V, E)\) as follows: \(V = \{k_1, k_2, \ldots, k_n\}\) and there is a directed edge from \(k_i\) to \(k_j\) if the algorithm for CEP has determined that \(k_i < k_j\) (for any \(1 \leq i, j \leq n\)). This graph is constructible in \(O(n + T(n))\) time. We could obtain the elements of \(K\) in sorted order as follows: Find the smallest element \(x_1\) in \(O(n)\) time. Find the smallest among all the neighbors of \(x_1\); this will be \(x_2\). Find the smallest among all the neighbors of \(x_2\); this will be \(x_3\), and so on. The total time spent is clearly \(O(n + |V| + |E|) = O(n + T(n))\) □

**Note:** Realize that CEP can be solved in \(O(n \log n)\) time. Also, the above lower bound can be circumvented for the following two special cases: 1) If the elements of the sets \(S_1\) and \(S_2\) are integers of at most a polynomial magnitude, we could sort the two sets in linear time and hence could solve CEP in linear time as well; 2) If the two sets are not of nearly the same size, the lower bound may not hold; for instance if one of the sets is of constant size, CEP can be solved in linear time. If \(|S_1| \geq |S_2|\), we believe that \(\Omega(|S_1| \log |S_2|)\) is a lower bound for CEP. Clearly, CEP can be solved in time \(O(|S_1| \log |S_2|)\).

## 3 SHRUTI — a model for reflexive reasoning

**SHRUTI** is a neural network model that can encode a class of rules and facts (see below) using only a linear number of nodes in \(|KB|\) and answer a class of queries in time proportional to the depth of the shortest derivation of the query.

Rules encoded by **SHRUTI** have the following form:\(^5\)

\(^5\)**SHRUTI** can also deal with soft/evidential rules, but for the purpose of this paper we will not consider such rules.
\[ \forall x_1, \ldots, x_m [P_1(...) \land P_2(...) \ldots \land P_n(...) \Rightarrow \exists z_1, \ldots, z_l Q(...)] \]

where the arguments of \( P_i \)'s are elements of \( \{x_1, \ldots, x_m\} \), and an argument of \( Q \) is either an element of \( \{x_1, \ldots, x_m\} \), an element of \( \{z_1, \ldots, z_l\} \), or a constant.

Facts encoded by \textsc{shruti} are partial or complete instantiations of predicates. Thus facts are atomic formulae of the form \( P(t_1, t_2 \ldots t_k) \) where \( t_i \)'s are either constants or distinct existentially quantified variables.

Queries have the same form as facts. A query, all of whose arguments are bound to constants corresponds to the \textit{yes-no} query: ‘Does the query follow from the rules and facts encoded in the KB?’ A query with existentially quantified variables, however, has two interpretations. For example, the query \( P(a, x) \), where \( a \) is a constant and \( x \) is an existentially quantified argument, may be viewed as the \textit{yes-no} query: ‘Does \( P(a, x) \) follow from the rules and facts for some value of \( x \)?’ Alternately this query may be viewed as the \textit{wh}-query: ‘For what values of \( x \) does \( P(a, x) \) follow from the rules and facts in the KB?’

### 3.1 An overview of \textsc{shruti}

The following provides a simple overview of \textsc{shruti}. It illustrates how simple rules and facts are encoded in \textsc{shruti} and how a query is posed to and processed by \textsc{shruti}. This example does not deal with rules with multiple antecedents and rules containing repeated variables or constants in the consequent. A detailed specification of the encoding may be found in (SA93).

The network shown in Fig. 1a encodes the following \textit{rules} and \textit{facts}:

1. \( \forall x, y, z \text{ give}(x,y,z) \Rightarrow \text{own}(y,z) \)
2. \( \forall x, y \text{ buy}(x,y) \Rightarrow \text{own}(x,y) \)
3. \( \forall x, y \text{ own}(x,y) \Rightarrow \text{can-sell}(x,y) \)
4. \( \text{give}(John, Mary, Book1) \)
5. \( \exists (x) \text{ buy}(John, x) \)
6. \( \text{own}(Mary, Ball1) \).
Figure 1: (a) An example encoding of rules and facts. (b) Activation trace for the query can-sell(Mary,Book1)?.

The encoding makes use of two types of nodes: $\rho$-btu nodes (depicted as circles) and $\tau$-and nodes (depicted as pentagons). These nodes have the following idealized behavior: If a $\rho$-btu node $A$ is connected to another $\rho$-btu node $B$, then the activity of node $B$ synchronizes with the activity of node $A$. In particular, a periodic firing of $A$ leads to a periodic and in-phase firing of $B$. We assume that $\rho$-btu nodes can respond in this manner as long as the period of firing, $\pi$, lies in the interval $[\pi_{\text{min}}, \pi_{\text{max}}]$. This interval can be interpreted as defining the frequency range over which $\rho$-btu nodes can sustain a synchronized response. A $\tau$-and node behaves like a temporal AND node, and becomes active on receiving an uninterrupted pulse train. On becoming active, a $\tau$-and node produces a pulse train similar to the input pulse train. A third type of node namely, the $\tau$-or node (depicted as a triangle) is also used in SHRUTI. A $\tau$-or node becomes active on receiving any activation and produces an output pulse train of width and period equal to greater than $\pi_{\text{max}}$. Fig. 2 summarizes the behavior of these nodes for the idealized case of oscillatory inputs.

The encoding also makes use of inhibitory modifiers — links that impinge upon and inhibit other links. A pulse propagating along an inhibitory modifier will block a pulse
Figure 2: Behavior of the $\rho$-btu, $\tau$-and and $\tau$-or nodes in the reasoning system.

propagating along the link it impinges upon. In Fig. 1a, inhibitory modifiers are shown as links ending in dark blobs.

Each entity in the domain is encoded by a $\rho$-btu node. An $n$-ary predicate $P$ is encoded by a pair of $\tau$-and nodes and $n$ $\rho$-btu nodes, one for each of its $n$ arguments. One of the $\tau$-and nodes is referred to as the enabler, $e:P$, and the other as the collector, $c:P$. In Fig. 1a, enablers point upward while collectors point downward. The enabler $e:P$ becomes active whenever the system is being queried about $P$. On the other hand, the system activates the collector $c:P$ of a predicate $P$ whenever the system wants to assert that the current dynamic bindings of the arguments of $P$ follow from the knowledge encoded in the system.

A rule is encoded by connecting the collector of the antecedent predicate to the collector of the consequent predicate, the enabler of the consequent predicate to the enabler of the antecedent predicate, and by connecting the arguments of the consequent predicate to the arguments of the antecedent predicate in accordance with the correspondence between these arguments specified in the rule. A fact is encoded using a $\tau$-and node that receives an input from the enabler of the associated predicate. This input is modified by inhibitory modifiers from the argument nodes of the associated predicate. If an argument is bound to an entity in the fact then the modifier from such an argument node is in turn modified by an inhibitory modifier from the appropriate entity node. The output of the $\tau$-and node is connected to the collector of the associated predicate.
The Inference Process

Posing a query to the system involves specifying the query predicate and the argument bindings specified in the query. This is done as follows: Choose an arbitrary point in time—say, \( t_0 \)—as the point of reference for initiating the query (it is assumed that the system is in a quiescent state). The query predicate is specified by activating the enabler of the query predicate with a pulse train of width and periodicity \( \pi \) starting at time \( t_0 \).

The argument bindings specified in the query are communicated to the network as follows: Let the argument bindings in the query involve \( n \) distinct entities: \( c_1, \ldots, c_n \). With each \( c_i \), associate a delay \( \delta_i \) such that no two delays are within \( \omega \) of one another and the longest delay is less than \( \pi - \omega \). As mentioned earlier, \( \omega \) is the width of the window of synchrony and \( \pi \) is the period of oscillation. Each of these delays may be viewed as a distinct phase within the period \( t_0 \) and \( t_0 + \pi \). Now the argument bindings of an entity \( c_i \) are indicated to the system by providing an oscillatory spike train of periodicity \( \pi \) starting at \( t_0 + \delta_i \), to \( c_i \) and all arguments to which \( c_i \) is bound. This is done for each entity \( c_i \) (\( 1 \leq i \leq n \)) and amounts to representing argument bindings by the in-phase or synchronous activation of the appropriate entity and argument nodes.

We illustrate the reasoning process with the help of an example. Consider the query \( \text{can-sell}(\text{Mary, Book1}) \)? (i.e., ‘Can Mary sell Book1?’) This query is posed by providing inputs to the entities \( \text{Mary} \) and \( \text{Book1} \), the arguments \( \text{p-seller}, \text{cs-obj} \) and the enabler \( e:\text{can-sell} \), as shown in Fig. 1b. \( \text{Mary} \) and \( \text{p-seller} \) receive in-phase activation and so do \( \text{Book1} \) and \( \text{cs-obj} \). Let us refer to the phase of activation of \( \text{Mary} \) and \( \text{Book1} \) as \( p_1 \) and \( p_2 \) respectively. As a result of these inputs, \( \text{Mary} \) and \( \text{p-seller} \) will fire synchronously in phase \( p_1 \) of every period of oscillation, while \( \text{Book1} \) and \( \text{cs-obj} \) will fire synchronously in phase \( p_2 \) of every period of oscillation. The node \( e:\text{can-sell} \) will also oscillate and generate a pulse train of periodicity and pulse width \( \pi \). The activations from the arguments \( \text{p-seller} \) and \( \text{cs-obj} \) reach the arguments \( \text{owner} \) and \( \text{o-obj} \) of the \( \text{own} \) predicate, and consequently, starting with the second period of oscillation, \( \text{owner} \) and \( \text{o-obj} \) become active in \( p_1 \) and \( p_2 \), respectively. At the same time, the activation from \( e:\text{can-sell} \) activates \( e:\text{own} \). The system has essentially, created dynamic bindings for the arguments of predicate \( \text{own} \). \( \text{Mary} \) has been bound to the argument \( \text{owner} \), and \( \text{Book1} \) has been bound to the argument \( \text{o-obj} \). These newly created bindings in conjunction with the activation of \( e:\text{own} \) can be thought of as encoding the query \( \text{own}(\text{Mary, Book1}) \)? (i.e., ‘Does Mary own Book1?’)! The \( \tau \)-and node associated with the fact \( \text{own}(\text{Mary, Ball1}) \) does not match the query and remains inactive. The activations from \( \text{owner} \) and \( \text{o-obj} \) reach the arguments \( \text{recip} \) and \( \text{g-obj} \) of \( \text{give} \), and \( \text{buyer} \) and \( \text{b-obj} \)
of buy respectively. Thus beginning with the third period of oscillation, arguments recip and buyer become active in $p_1$, while arguments $g$-obj and $b$-obj become active in $p_2$. In essence, the system has created new bindings for the predicates give and buy that can be thought of as encoding two new queries: $\text{give}(x,\text{Mary},\text{Book}1)$? (i.e., 'Did someone give Mary Book1?'), and $\text{buy}(\text{Mary},\text{Book}1)$?. Observe that now the $\tau$-and node associated with the fact $\text{give}(\text{John},\text{Mary},\text{Book}1)$—this is the $\tau$-and node labeled $F1$ in Fig. 1a—becomes active as a result of the uninterrupted activation from $c: \text{give}$. The inhibitory inputs from recip and $g$-obj are blocked by the in-phase inputs from Mary and Book1, respectively. The activation from this $\tau$-and node causes $c: \text{give}$, the collector of give, to become active. The output from $c: \text{give}$ in turn causes $c: \text{own}$ to become active and transmit an output to $c: \text{can-sell}$. Consequently, $c: \text{can-sell}$, the collector of the query predicate can-sell, becomes active (refer to Fig. 1b) resulting in an affirmative answer to the query $\text{can-sell}(\text{Mary},\text{Book}1)$?.

Conceptually, the proposed encoding of rules creates a directed inferential dependency graph: Each predicate argument is represented by a node in this graph and each rule is represented by links between nodes denoting the arguments of the antecedent and consequent predicates. In terms of this conceptualization, it should be easy to see that the evolution of the system's state of activity corresponds to a parallel breadth-first traversal of the directed inferential dependency graph. This means that i) a large number of rules can fire in parallel and ii) the time taken to generate a chain of inference is independent of the total number of rules and just equals $l\pi$ where $l$ is the length of the chain of inference and $\pi$ is the period of oscillatory activity. The example discussed above assumed that each predicate was instantiated at most once during the inference process. In the general case, where a predicate may be instantiated several times during an episode of reasoning, the time required for propagating bindings from a consequent predicate to antecedent predicate(s) is proportional to $k\pi$, where $k$ is the number of dynamic instantiations of the antecedent predicate when the bindings are being propagated.

3.2 A characterization of SHRUTI's inferential power

A characterization of the class of queries that can be processed by a SHRUTI-like system in a reflexive manner is given in [Shastri 1993]. A description of this class is facilitated by the following definitions (from [Shastri 1993]):

- Any variable that occurs in multiple argument positions in the antecedent of a rule is a pivotal variable.
A rule is balanced if all pivotal variables occurring in the rule also appear in its consequent.

For example, the rule \( \forall x, y, z \ P(x, y) \land R(x, z) \Rightarrow S(x, z) \) is balanced, but the rule \( \forall x, y, z \ P(x, y) \land R(x, z) \Rightarrow S(y, z) \) is not.

Consider a query \( Q \) and a KB consisting of facts and balanced rules. A derivation of \( Q \) obtained by backward chaining is threaded if all pivotal variables occurring in the derivation get bound and their bindings can be traced back to the bindings introduced in \( Q \).

Given a KB consisting of facts and balanced rules, a reflexive query is one for which there exists a threaded proof.

It can be shown that the worst-case time for answering a reflexive yes-no query, \( Q \), is proportional to \( V|In|^V d \), where:

- \( V \) is as follows: Let \( V_i \) be the arity of the predicate \( P_i \). Then \( V \) equals \( \max(V_i) \), \( i \) ranging over all the predicates occurring in the KB.
- \( |In| \) is the number of distinct constants in \( Q \) (\( |In| \leq V \)).
- \( d \) equals the depth of the shallowest derivation of \( Q \) given the KB.\(^6\)

Observe that the worst-case time is i) independent of the size of the KB, ii) polynomial in \( |In| \) and iii) only proportional to \( d \).

An answer to a \( wh \)-query can also be computed in time proportional to \( V|In|^V d \), except that \( |In| \) now equals the arity of the query predicate \( Q \).

The space requirement is linear in the size of the KB and polynomial in \( |In| \). This includes the cost of encoding the KB as well as the cost of maintaining the dynamic state of the 'working memory' during reasoning.

The above result offers a worst-case characterization which assumes that during the derivation, all variables will get instantiated with all possible bindings involving constants in \( Q \). This will not be the case in a typical situation. As pointed out in (S93), in a typical episode of reasoning the actual time may seldom exceed 50\( d \).

### 3.3 CEP and reflexive reasoning

Consider the unbalanced rule:

\[
P(x) \land Q(x, y) \Rightarrow R(y)
\]

\(^6\)This assumes that the maximum arity of predicates in the KB is a constant.
for relations $P, Q,$ and $R$. Let $R(a)$ be the query. Clearly, if all the tuples in $Q$ were of the form $Q(., a)$, answering the query reduces to CEP. Thus if $|P| = |Q| = n$, $\Omega(n \log n)$ will be a lower bound on the processing time of the query. As a simple corollary it follows that any parallel algorithm for processing the query $R(a)$ will need $\Omega(\log n)$ time, given only $n$ processors. Thus we have the following

**Lemma 3.1** Any linear sized network model for reasoning can not make inferences in time independent of the size of the KB if it admits unbalanced rules.

The above lemma shows that the constraint that rules be balanced is a necessary constraint for reflexive reasoning and not merely an artifact of the SHRUTI design.

### 3.4 CEP and Database JOIN

JOIN is an important operation to be performed in relational database systems. Let $R$ and $S$ be two given relations with arity $k$ and $\ell$ respectively. $R$ can be thought of as a table of $k$-tuples, each column corresponding to some domain of values. The $\theta$-join of $R$ and $S$ on columns $i$ and $j$ is defined to be those tuples in the cartesian product of $R$ and $S$ such that the $i$th component of $R$ stands in relation $\theta$ to the $j$th component of $S$ [Ullman 1988]. When $\theta$ stands for $=$, the JOIN operation is called *EQUIJOIN*. In the worst case, the size of the JOIN of the two relations can be $|R| \cdot |S|$ where $|R| (|S|)$ is the number of tuples in $R$ ($S$).

Consider the problem of deciding if the EQUIJOIN of two given relations $R$ and $S$ on columns $i$ and $j$ is nonempty. Clearly, this problem reduces to checking if column $i$ of $R$ and column $j$ of $S$ are disjoint. If $|R| = |S| = n$, the lower bound for CEP implies that this decision problem needs $\Omega(n \log n)$ time sequentially. Also, any parallel algorithm for this problem that uses only $O(n)$ processors will need $\Omega(\log n)$ time.

### 4 Conclusions

In this paper we have proved a lower bound for the Common Element Problem and have demonstrated the applicability of this lower bound in two different areas of computing, i.e., reasoning and databases. The lower bound in particular implies that any model of reasoning that is of size only proportional to the size of the knowledge base, cannot hope to make inferences on all queries whose derivation involves unbalanced rules, in time independent of the size of the knowledge base. As a consequence, we conclude that the constraints imposed
on the SHRUTI model are indeed necessary and hence the SHRUTI model be a stronger predictor of the nature of reflexive reasoning processes in humans.
