A New Species of *Discinites* (Noeggerathiales) Associated with a New Species of *Yuania* from the Lower Permian of Inner Mongolia, China

Abstract

A fructification *Discinites baculiformis* sp. nov. and the foliage *Yuania wudensis* sp. nov. are described from the lower Permian Shanxi Formation of Wuda, Inner Mongolia, North China. *Discinites baculiformis* sp. nov. is at least 31 cm long and 1.5–1.8 cm wide. It has more than 78 whorls of sporophylls, each with ca. 85 sporangia on the adaxial side, a total of more than 6630 sporangia. The impression of the sporophyll epidermis is preserved, and cells are visible. *In situ* trilete spores are detected. The new species represents the longest strobilus with the largest number of whorls of sporophyll disks so far known in the genus. *Yuania wudensis* sp. nov. has unbranched rachises, with alternate to subopposite elongate ellipsoidal pinnae. Epidermal cells are rectangular, long, and narrow. The two new species might represent the fructification and foliage of the same parent plant, since there is no other noeggerathialean member in the taphonomic plant community. The association is comparable with the association of *Discinites* and *Russellites* from the Permian of Texas.

Introduction

Discinites includes fossil bisporangiate strobili with sporangia arranged adaxially on a circular, fused sporophyll. The genus has been recorded from the Carboniferous of the Bohemian Massif, Czech Republic (Feismantel 1880; Němec 1937, 1941; Šimůnek and Bek 2003), the Carboniferous of the Netherlands (Hirmer and Guthörl 1940) and Germany (Remy and Remy 1956), the Carboniferous of Michigan (Arnold 1944, 1949) and lower Permian of Texas, U.S.A. (Mamay 1954), the Permian of Saudi Arabia (Hill and El-Khayal 1983), and the Carboniferous and Permian of China (Bohlin 1971; Gu and Zhi 1974; Wang 2000; Wang and Shen 2000).

Before the establishment of the family Discinitaceae in the order Noeggerathiales (Gao and Thomas 1994), *Discinites* had been assigned directly to the Noeggerathiales (Gothan and Weyland 1973; Taylor 1981), to the Noeggerathiineae (as a subdivision within the Filicales; Hirmer and Guthörl 1940), or to the order Discinitales in the Noeggerathiophyta (as a division; Zimmermann 1959; Boureau 1964). Palaeobotanists have always focused attention on *Discinites* as a well-recognized noeggerathialean fructification in terms of the structure of the strobilus and the morphology of the sporophylls and *in situ* spores. However, this extinct plant group is insufficiently known, and its systematic position is still uncertain. Progress has been made in recent years in understanding the diversity and other properties of the group (Gao and Thomas 1994; Wang 2000; Wang and Shen 2000; Šimůnek and Bek 2003; Wang et al. 2004; Bek and Šimůnek 2005).

In this article, a new species of *Discinites* and a new species of *Yuania* are described on the basis of well-preserved specimens collected from the Wuda Coalfield, which is near the locality of the type specimen of *Discinites sinensis* (Wang 2000). Both new species display novel features: an unanticipated length in the *Discinites* strobilus and the morphology of the epidermal cells in *Yuania* pinnae, and consequently they expand our knowledge of *Discinites* and *Yuania* in both China and the Cathaysian flora.

Material and Methods

The fossils described here were collected from the early Permian Shanxi Formation of the Wuda coalfield of southwest Inner Mongolia, North China (fig. 1) at 39°28'53"N, 106°38'08"E during a geological investigation to search for more materials of the petrified *Discinites sinensis* (Wang 2000). They are preserved in a black shale, and splitting of this matrix has produced both a compression and an impression counterpart. Some degagement of the specimens was necessary. This was successfully done with a medical syringe needle. Maceration of portions of sporophylls, sporangia, and laminae, unfortunately, yielded neither cuticles nor spores. Fragments of the strobilus and lamina were prepared for SEM observations. Samples were coated with gold using an Emscope sputter coater and examined with a JSM-6300/LEO 1530VP scanning electron microscope. Some specimens were examined and photographed with a stereomicroscope (Leica DC300). All the figured specimens are deposited in the palaeobotanical collections of the Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, China (catalog numbers PB20252–20271).

Fig. 1 Map showing the localities of *Discinites baculiformis* sp. nov. and *Yuania wudensis* sp. nov.

Systematic Description

Order—Noeggerathiales Němejc 1931

Family—Discinitaceae Gao and Thomas 1994

Genus—Discinites Feistmantel (1879) 1880

Type species—Discinites bohemicus Feistmantel 1880

Discinites baculiformis Wang, Pfefferkorn,
Feng and Shen sp. nov.

Holotype. PB20252a, 20252b (fig. 2a, 2b).

Paratypes. PB20253–20258, 20268 (fig. 3a, 3c–3g).

Repository. Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, China.

Type locality. Wuda, Inner Mongolia, China.

Stratigraphic position. Shanxi Formation.

Age. Early Permian (Asselian to Sakmarian).

Etymology. The specific name is derived from the Latin *baculum* (rod) implying that the strobilus is rod shaped, thin, and long as a whole.

Diagnosis. Strobilus more than 31 cm long, 1.5–2.0 cm in diameter, with a long pedicel; axis ca. 3.5–4.0 mm wide. Bases of sporophylls decurrent around the axis; proximal parts united to form a disk, with a right angle to the axis; distal parts upturned and parallel to the axis, deeply dissected into more than 50 teeth ca. 8–10 mm long and 2 mm wide at the base, with a single vein in the middle of the teeth. Sporangia elliptical, ca. 2.5–3.0 mm long and 0.7–1.0 mm wide, alternate and radiately arranged, forming four to five circles on the adaxial side of the disks. There are ca. 80–90 sporangia per disk. Epidermal cells of sporophyll are rectangular, 20–50 μm wide and 60–150 μm long, or polygonal,

20 $\times$ 40 μm to 40 $\times$ 85 μm in size, with long axes parallel to the radius of the disk. Spores are in tetrads. The spores are ca. 50–80 μm in diameter.

Description. From more than 50 specimens of *Discinites baculiformis* sp. nov., one was chosen as the holotype and seven as paratype specimens that best show the basal disk and apical teeth of the sporophylls and the position of the axis as well as the shape, size, and distribution of the sporangia.

The holotype specimen (fig. 2a, 2b) consists of the part and counterpart of a single strobilus, compressed parallel to the axis. It is incomplete apically and basally. It is ca. 15 mm in diameter at the upper part and ca. 20 mm at the lower end and ca. 250 mm long. The axis is 3.5 mm wide in the middle. The disks of sporophylls are ca. 3–4 mm apart vertically, with slightly wider separation in the lower part than the upper part. There are at least 60 disks of sporophylls recognizable on the preserved part of the strobilus. The middle upper part, i.e., about three-fourths of the specimen from the base upward, is laterally broken on the holotype (fig. 2a, frame), but this part of the strobilus is well preserved on the counterpart (fig. 2b, frame; fig. 2c), showing that these two parts form a continuous strobilus. The characteristic sporangial arrangement of *Discinites* is well demonstrated at the uppermost and the lower part of the holotype (fig. 2a, 2d). The connection of the sporophyll disk with the axis is visible at the middle lower part of the holotype (fig. 2a, upper left arrowhead; fig. 2d) and some other specimens (fig. 3a, 3f), showing that the very base of sporophyll is slightly decurrent.

The distal parts of the sporophylls are usually not well preserved. After the matrix (fig. 2a, lower left arrowhead) was removed, the upturned distal parts of sporophylls were

clearly visible (fig. 3b). They are upturned at a right angle, extend upward to overlap the next whorl of sporophylls, and are parallel with the axis of the strobilus. They are obviously longer than the spaces between the disks. Occasionally, in cases where the fracture pathway of the strobilus passes longitudinally through the edge of the sporophyll disk (fig. 3e), the apical teeth of sporophylls are clearly visible. The periphery of a fragmentary disk forms an arc, where the number of teeth can be counted. Judging from the width of such arcs in relation to the circumference of the disk, there are ca. 50 teeth per disk. A good example is shown in figure 3c, where there are ca. 12 teeth recognizable on the well-preserved quarter part of the disk of sporophylls. There is a single vein in the middle of the apical teeth of the sporophylls, the same length as the teeth themselves.

The specimen in figure 3d clearly shows the articulate sporophyll disks. The apical teeth of sporophylls are not preserved. The specimen in figure 3g demonstrates the basal pedicel of the strobilus. The strobilus shown in figure 6b (to the left) is 310 mm long, excluding the unpreserved base and apex, 18 mm wide at the lower part, and 15 mm wide at the upper part. The distance between two whorls of sporophyll disk is ca. 4 mm on average, and consequently ca. 78 whorls of disks are preserved in total.

Epidermal cells of the sporophylls vary in shape along with their position. As shown in figure 4c, 4e, and 4j, those besides the sporangia are long and narrow, usually rectangular, with the ends pointed, and with the longer sides four to seven times the length of the short sides. They are normally 80–140 μm long and 20–35 μm wide. Cells are arranged with their longer axes parallel to the radial direction of the sporophyll disk (fig. 4o). The cells on the area at the point of attachment of a sporangium (fig. 4j, 4m) are short and wide, varying remarkably in size and shape. They may range from 20 $\times$ 40 μm to 40 $\times$ 85 μm in size. They are basically irregularly hexagonal in shape but occasionally more irregular. Neither ornamentations nor thickenings occur on the periclinal or anticlinal walls (fig. 4b–4o). Stomata have not been detected on the surface of sporophylls with certainty. The more than 150-mm² area of the surface of the sporophylls was examined for stomata, and only two (fig. 4h, 4i) could be found. However, these could also be artifacts of preservation, because numerous places can be observed where grains of extraneous matter have been adpressed to the surface.

The sporangia are alternately and radiately arranged, with an inclination outward from the axis (fig. 2a, 2d; fig. 4a, 4b). They are basically elliptical, measuring 2.5–3.0 mm in length and 0.7–1.0 mm in diameter. They vary more or less in form and size due to various degrees of compression. They may be slightly bigger as a result of a high degree of compression, and this might be the case for those sporangia close to the axis of the strobilus (fig. 2d, lower black arrowhead; fig. 4a, lower arrowhead), or slightly smaller due to minimal compression. This might be the case of those sporangia far from the strobilus axis (fig. 2d, upper black arrowhead; fig. 4a, upper arrowhead). Mostly the base and apex are tapering, but specimens very close to the axis usually have a wide base and a tapering apex. In good specimens, certain compressions may be preserved with a transverse section of a sporangium, so that the spores are visible (fig. 4c–4g). Judging from the

areas where the sporangia can be counted and from the sizes of these areas in relation to the total areas of the disks, there are probably 80–90 sporangia attached to each disk. For instance, there are ca. 42 sporangia counted on about half a disk of sporophylls (fig. 2a, lower right arrowhead), whereas there are ca. 22 sporangia counted on about one quarter-disk of sporophylls (fig. 2a, upper right arrowhead).

Maceration of coaly substances removed from the strobilus at the supposed position of sporangia did not yield any results. However, *in situ* spores are recognizable in broken sporangia under the stereomicroscope (fig. 4c–4g). The spores are still in tetrads and of the trilete type, ranging between 30–80 μm in diameter.

Comparison. Twenty-three species of *Discinites* have been described so far from the Carboniferous and Permian of Europe, North America, China, and Saudi Arabia (table 1). *Discinites baculiformis* sp. nov. is more than 310 mm in length and 15–18 mm in width, more slender than all the 23 known species. The longest ones previously known are *Discinites raconicensis* (Bek and Šimůnek 2005), which is 210 mm in length. The thinnest one previously known is *Discinites delectus* (Arnold 1949), which is 17 mm wide, similar in width to the new species. In terms of the length-to-width ratio, *D. baculiformis* sp. nov. is more than three times slenderer than *D. delectus*. Moreover, the number of sporangia bearing on each sporophyll disk in *D. delectus* is ca. 60, whereas it is 80–90 in the new species. In *D. baculiformis* sp. nov., the total number of sporophyll disks on the strobilus is probably more than 78. Such a quantity of sporophyll disks on a strobilus is significantly larger than those of previous described species of *Discinites* (table 1). Species for which the number of sporophyll disks has been estimated include *D. hanchengensis*, *D. sinensis*, *Discinites bohemicus*, *D. egregius*, *D. hlizae*, *D. major*, *D. nemejcii*, *D. raconicensis*, and *D. cf. raconicensis*. The sporophyll disk numbers of *D. raconicensis* and *D. cf. raconicensis* are the largest, ca. 26, which is only one-third of that of the new species.

Discinites baculiformis sp. nov. is similar to *D. sinensis* Wang (2000) from the lower Permian of Shizuishan, Ningxia, with respect to strobilus diameter (17 and 20 mm, respectively) and the distance (both are 4 mm) between two adjacent disks of sporophylls, and the localities of the two species are in the same area (fig. 1). However, the sporangia of *D. sinensis* are much larger (4 mm long and 1.5 mm in diameter) than those of the new species (2.5–3 mm long and 0.7–1.0 mm in diameter), and the number of sporangia per disk of *D. sinensis* (30–35) is definitely much smaller than that of the new species (80–90). Additionally, the *in situ* spores of *D. sinensis* are of the *Deltoidospora* type, while those of *D. baculiformis* are only known to be of the trilete type. These differences are so significant that the fossil described here must be considered a new species.

Discinites dentilongus (Gao and Thomas 1994), from the early Permian of Taiyuan, resembles the new species in having the same number of similarly deep-toothed sporophylls, but differs from the new species in having considerably fewer and smaller sporangia per disk and wider, shorter strobili.

Discinites delectus, from the early Pennsylvanian of the Michigan coal basin (Arnold 1944, 1949), has approximately the same width of strobilus and distance between adjacent

Fig. 2 General morphology of *Discinites baculiformis* sp. nov. *a, b*, Part and counterpart of the holotype. The frame in *a* indicates an area where the connection between the upper and lower parts of the strobilus is not clearly shown, but it is reliably demonstrated in the counterpart specimen *b* (within the frame). In *a*, the lower left arrowhead indicates an area where the apical teeth of sporophylls are not well exposed but are visible after the matrix is removed, as shown in fig. 3*b*; the lower right arrowhead indicates an area where half of a sporophyll disk is well exposed,

disks of sporophylls as the new species, and so it appears similar in gross morphology, excluding the shorter length of the strobilus, which might be due to preservation. It differs from *D. baculiformis* sp. nov. in that the diameter (1.7 mm) of its sporangia is much larger than that of the new species (0.7–1.0 mm), and its sporangial number per disk (ca. 60) is much less than that of the new species (80–90).

Genus—*Yuania* Sze, emend. Du and Zhu 1982

Species—*Yuania wudensis* Wang, Pfefferkorn, Feng and Shen sp. nov.

Syntypes. PB20259–20271 (figs. 5a–5h, 6b–6d, 7a).

Repository. Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, China.

Type locality. Wuda, Inner Mongolia, China.

Stratigraphic position. Shanxi Formation.

Age. Early Permian (Asselian to Sakmarian).

Etymology. The species is named after the city of Wuda.

Diagnosis. Rachis unbranched, 4.0–8.3 mm wide and tapering gently upward to 1.0 mm or less in width. Pinnules alternate to subopposite and decurrent, with broad, obliquely clasping base. Pinnule insertion on rachis distant from each other (15 mm apart) to crowded, most crowded terminally; angles of pinnules insertion acute, ca. 45°–90°, decreasing toward frond apex. Pinnules linear to oblong, 10–45 mm long and 2.5–17 mm wide, about two to four times as long as they are wide, with the proportionately widest pinnules occurring at frond bases; pinnule tips slightly wider than bases. Pinnules overlapping or separate. Veins dense and slender, with those in the base of pinnules slightly thicker; 12–20 veins entering pinnule bases, approximately half dichotomizing within basal one-third of lamina, some dichotomizing a second time. Twenty-five to 30 veins per pinnule counted at widest part of lamina, evenly spaced, converging toward pinnule apices. Epidermal cells rectangular, 25–40 μ m wide and 40–140 μ m long. No stomata detected.

Description. Specimens of *Yuania* have been regarded as either pinnate fronds (Mamay 1968; Du and Zhu 1982) or shoots with leaves arranged in flat planes (Gu and Zhi 1974; Wang and Wang 1987). The present authors use the terminology of Du and Zhu (1982) and Mamay (1968), which accords with the latest description of *Noeggerathia* (Šimůnek and Bek 2003), which is the representative member of the *Noeggerathiales*.

There are a larger number of fragments with pinnules attached. Twelve of them are selected as syntypes. The rachial fragment shown on figure 5h is 20 cm long, with a greatest width of 5 cm at the upper part of the frond. The axis is ca. 5 mm wide at the basal part and gradually becomes more

slender apically. The basal pinnules are ca. 12 mm wide and 24 mm long, and the apical pinnules are ca. 12 mm wide and 33 mm long. They are about two to three times as long as they are wide, and become wider basally. The frond tips each consist of an axis less than 1 mm wide and have very crowded pinnules that obviously terminate the frond (figs. 5a, 6c). The pinnules are narrow and long, about four times as long as they are wide, decreasing rapidly in size toward the apex. Figures 5d, 6a, and 6b represent the basal part of the fronds, each of which has an extremely sturdy axis compared to the size of the attached pinnules. Most of the pinnules are wide and short, about two to three times as long as they are wide. They are separated by a distance of ca. 12–14 mm on the rachis. In particular, the frond in figure 6a, 6b has a long pedicel at the base, on which no pinnules are detected. Rachial fragments, as shown in figure 5b, 5c, with a ratio of length to width intermediate between these two extremes, are abundant, with a width of 10–16 mm being predominant. They probably represent the middle part of the frond. Figure 5c may be a fragment from the very middle part of the frond, with pinnules evenly arranged and their form and size even, too. Figure 5b may be a fragment of the middle upper part of the frond; the pinnules are more crowded, proportionately narrower and longer apically, and the size decreases apically.

Regardless of the position on the rachis, the lateral margins of the pinnules are always entire, curving gently and equally from the base to the tip. They are basally very broad and attached to the rachis in an obliquely clasping manner. Pinnule sizes range from 12 to 50 mm in length and 3.5 to 16 mm in width, are generally widest in the middle, and have a length-to-width ratio between 2 : 1 and 4 : 1.

The apices of pinnules are universally truncated (figs. 5e–5g, 6d). This is the most characteristic morphological feature of the pinnule. The truncated pinnule apices are slightly concave, with the truncated margin virtually perpendicular to the long axes of the pinnules. The width of the apex is slightly larger than half the width of the pinnule at the basal part of the frond, but gradually decreases upward to only one-half to one-third of the pinnule width at the middle upper part of the frond. Occasionally, several pinnules show lobed apical margins (fig. 5c, arrowhead), but this is probably a result of preservation, because all other pinnules are apically truncated.

The pinnules are inserted alternately (fig. 5c). In some specimens where the pinnules are close together (fig. 5b, 5h), it appears that some pinnules have a subopposite arrangement, but there is no evidence of clearly opposite foliation. The angles of pinnule insertion are ca. 70° at the middle part of the frond, decreasing toward the frond apex to ca. 45°

so that the number of sporangia may be counted, and it is shown that the sporangia close to the axis of the strobilus are more highly compressed, appearing relatively larger in size than those far from the axis, which are only slightly compressed and appear small in size; the upper left arrowhead indicates an area where the connection of a sporophyll with the axis of the strobilus is clearly shown; the upper right arrowhead indicates a one-fourth part of sporophyll disk that is well preserved with the sporangia countable. $\times 0.8$; a, PB20252a; b, PB20252b. c, Partial enlargement of the area within the frame of the counterpart shown in b, showing the typical sporangial arrangement of *Discinites*. $\times 3$; PB20252b. d, Partial enlargement of the middle lower part of the holotype in a, showing the typical sporangial arrangement of *Discinites*. White arrowheads correspond, respectively, to the lower right and upper left arrowheads in a. The sporangium close to the axis (lower black arrowhead) is a little larger than the one far from the axis (upper black arrowhead). $\times 2$; PB20252a.

Fig. 3 General morphology of the strobilus. *a*, Specimen with the fracture pathway passing through the axis of the strobilus in the lower part and through the edge of the sporophyll disk in the upper part. The connection of sporophylls with the axis is clearly visible. $\times 1$; PB20253. *b*, Apical teeth of sporophylls of the holotype at the lower left arrowhead in fig. 2*a* are well exposed after the matrix is detached. $\times 8$; PB20252*a*. *c*, Isolated sporophyll disk fragment showing that there is a single vein in the apical teeth of the sporophylls. $\times 2$; PB20254. *d*, Articulate character of the strobilus. The apical teeth of sporophylls are not preserved. $\times 1$; PB20255. *e*, Specimen with the fracture pathway passing through the apical teeth of sporophylls, which always extend upward and cover the upper neighboring sporophylls. $\times 1$; PB20256. *f*, Specimen with the fracture pathway passing through the axis in the lower part and the surface of the strobilus at the uppermost part. $\times 1$; PB20257. *g*, Strobilus with the basal long stalk preserved. $\times 0.7$; PB20258.

and increasing toward the base to 90° (fig. 6*a*, 6*b*). Pinnules are widely spaced at the base of the frond (fig. 5*d*; fig. 6*a*, 6*b*) and become crowded, so as to overlap each other and form an imbricate arrangement at the middle and upper part of the frond (fig. 5*a*–5*c*, 5*b*).

The venation of the pinnules consists of closely set parallel veins (figs. 5*a*–5*e*, 6*d*). There are 12–20 veins entering the base of the lamina. Some of them divide equally in the proximal half of the lamina (fig. 5*c*–5*d*) and then persist, evenly spaced, extending to the truncated apical margin, where they

Note. Primarily after Gao and Thomas (1994) and Bek and Šimůnek (2004). Data for *in situ* spores and the output of sporangia are from Remy and Remy (1956) and Balme (1995). P = Permian; P₁ = Early Permian; P₂ = Late Permian; C = Carboniferous; C₂ = Late Carboniferous. Measurements are based on the preserved parts of the strobili, and consequently the true dimensions/quantities should be larger than the results of the current calculation.

Fig. 5 General morphology of *Yuania wudensis* sp. nov. *a–d*, Fragmentary fronds showing, respectively, the apical (*a*), middle upper (*b*), middle (*c*), and basal (*d*) parts, with their pinnules varying in terms of the shape, size, ratio of length to width, density of arrangement, and thickness of the rachis. $\times 1$; *a*, PB20259; *b*, PB20260; *c*, PB20261; *d*, PB20262. *e–g*, General form, especially the truncate apices. $\times 1$; *e*, PB20263; *f*, PB20264; *g*, PB20265. *h*, Fragmentary specimen representing a frond from the lower to middle upper part. $\times 0.7$; PB20266.

Fig. 6 General morphology of *Yuania wudensis* sp. nov. and *Discinites baculiformis* sp. nov. *a*, Basal part of a frond, showing the morphology of basal pinnules. $\times 0.6$; PB20267. *b*, A strobilus (on the left), incomplete at the base and the apex, with a length of 31 cm and a width of 1.8 cm at the lower part and 1.5 cm at the upper part. The frond at the upper right is the counterpart of the upper part of the specimen in *a*. $\times 0.6$; PB20268. *c*, Morphology of the pinnules at the apex. $\times 1.1$; PB20269. *d*, Morphology of the pinnules at the middle part of a frond. $\times 1.05$; PB20270.

converge toward each other as the lamina decreases in width. In the distal half of the lamina (figs. 5d–5f, 7a), where the veins usually do not divide further, there are ca. 25–30 veins, while in some wider lamina the number of veins may reach 35 (fig. 5g).

The outline of epidermal cells is clearly recognizable under the stereomicroscope (fig. 7a, 7b) and with the SEM (fig. 7c–7h). Epidermal cells are generally rectangular in outline, sometimes with ends pointed, 18–42 μm in width and 40–118 μm in length, mostly ca. 30 μm wide and 50–80 μm long. Occasionally, cells 150 μm long can be recognized (fig. 7d). They are arranged with the long sides parallel to the veins. No stomata were detected in a more than 3-cm² lamina impression.

Comparison. *Yuania wudensis* sp. nov. demonstrates for the first time the forms of epidermal cells of *Yuania*, al-

though the outlines of epidermal cells are only revealed by their impressions rather than their true cuticles. In terms of the average pinnule size, *Yuania wudensis* sp. nov. may be the second smallest among known species of *Yuania* (table 2), with the generic type species *Yuania striata* Sze the smallest.

The pinnule characteristics of *Yuania gigantea* (Zhu and Hu 1982) all fall within the ranges of the new species (table 2). However, *Y. gigantea* is actually only defined according to the basal part of the frond (pl. 1, fig. 6 of Zhu and Hu 1982). The pinnules of *Y. gigantea* are only comparable with, but much larger than, those of the basal part of *Y. wudensis* sp. nov. Moreover, the pinnules of *Y. gigantea* are definitely decurrent. Such a characteristic is not as obvious in the pinnules of the new species, especially in the pinnules at the basal part of the frond (fig. 5d, 5e; fig. 6a, 6b).

Fig. 7 Cell morphology of the pinnules of *Yuania wudensis* sp. nov. All images are from specimen PB20271. *a*, A piece of pinnule with the impression of cells well preserved; scale bar = 5 mm; *b–h*, Enlargements of the pinnule in *a*, showing cell morphology and arrangement. *b*, Photograph under stereomicroscope showing the parallel veins and the cells between them; scale bar = 2 mm. *c–h*, SEM images with different degrees of enlargement, showing the cell morphology and arrangement; *c*, *e*, and *h* show that epidermal cells are all longitudinally arranged along with the parallel veins; *d*, *f*, and *g* show the variation in the length and width of cells. A cell could be much longer or wider than the neighboring ones. The scale bar in *c*, *e*, *f*, *h* is 100 μm ; that in *d* and *g* is 20 μm .

Table 2

Comparison of *Yuania wudensis* sp. nov. with Other Species of *Yuania* and *Russellites*

Characteristics of pinna	<i>Y. wudensis</i> sp. nov.	<i>Y. striata</i>	<i>Y. chinensis</i>	<i>Y. gigantea</i>	<i>Y. longifolia</i>	<i>Y. magnifolia</i>	<i>Russellites taeniata</i>
Length of pinna (mm)	12–50	11	20–65	40–45	50	25–60	20–115
Length/width	2–4	2	1–4	2–3	4	4–5	2–8
No. of veins	25–35	<20	20–30	35	26–31	20–30	8–58
Anastomosis of venation	None	None	None	None	Rare	None	Rare
Leaf scale			Subulate				
Epidermal cell	Enlongate/rectangular						
Reference	This article	Sze 1953	Du and Zhu 1982	Zhu and Hu 1982	Xiao 1985	Wang and Wang 1987	Mamay 1968

Note. *Russellites* Mamay 1968 was regarded as a synonymy of *Yuania* (Sze) by Du and Zhu (1982), but this was rejected by Mamay (1995). Without a direct comparison based on the holotype specimens of the two genera, it might be better to let them coexist for the time being.

Yuania longifolia (Xiao 1985) somewhat resembles the new species in the middle upper part of the frond in gross morphology. However, an anastomosis of venation is detected in its laminae, and the basal and apical parts of the *Y. longifolia* frond are not known.

Yuania magnifolia (Wang and Wang 1987) is represented by the middle and apical frond. It differs from the new species in its larger pinnule size, the looser arrangement of pinnules, and the wider angle of insertion of pinnules to the rachis.

Yuania chinensis (Du and Zhu 1982) is also represented by a complete pinnate frond. It differs from the new species in that the pinnules of *Y. chinensis* are slightly narrower and longer than those at the corresponding locations in *Y. wudensis* sp. nov. Interestingly, *Y. chinensis* is the only species of *Yuania* whose base is completely preserved, indicating that leaf scales occur at the base of the frond.

Du and Zhu (1982) regarded *Russellites taeniata* (Mamay 1968), from the lower Permian of Texas, as a synonym of *Yuania*, but Mamay (1990, 1995) rejected this opinion. The generic synonymy will be addressed elsewhere, but a comparison of the species is of importance in this context. The American species has a much larger frond and larger pinnules, shows a very wide range in the density of venation, and its veins anastomose. Consequently, it can be easily distinguished from *Y. wudensis* sp. nov.

Discussion

Discinites is well known from the Carboniferous and Permian of Europe, North America, Saudi Arabia, and China. Various types of sterile foliage are considered to belong to *Discinites* (Šimůnek and Bek 2003). They include *Russellites* (Mamay 1968) and *Eremopteris* (Arnold 1949) from the U.S.A., *Palaeopteridium* (Němjc 1937), *Saareopteris*, and *Rhacopteris* (Němjc 1941) from Europe, and *Tingia* (*T. carbonica* type), *Plagiozamites*, and *Yuania* (Wang and Shen 2000) from China.

Yuania wudensis sp. nov. and *Discinites baculiformis* sp. nov. are closely associated and are dominant in the same taphoflora. Such an association may be significant because the other members in the community, including *Taeniopteris*,

Sphenopteris, *Lepidodendron*, *Callipteris*, and the seed *Cornucarpus*, are known to belong to lycopside, cycads, ferns, or pteridosperms. *Yuania* and *Discinites* are, respectively, well known foliage and fructification of the Noeggerathiales, so that it is reasonable to deduce that *Y. wudensis* and *Discinites baculiformis* may be parts of the same plant. A precedent for this association is the close co-occurrence of the frond of *Russellites* with the fructification *Discinites* in the lower Permian of Texas (Mamay 1968). Whether or not *Russellites* is a synonym of *Yuania* (Du and Zhu 1982; Mamay 1990, 1995), they are very similar plants that certainly represent the same group. It is noteworthy that in the taphoflora from the lower Permian of Texas, *Discinites* and *Russellites*, respectively, represent the only noeggerathialean fructification and foliage, so that their association may be the same as the association of *D. baculiformis* sp. nov. and *Y. wudensis* sp. nov.

The epidermal cells of the sporophylls of *D. baculiformis* sp. nov. and the pinnules of *Y. wudensis* sp. nov. are similar in terms of their general form, size, and arrangement. Epidermal cells of both organs are rectangular and sometimes have pointed ends that are long and narrow. The abaxial surface of the sporophylls of *D. baculiformis* sp. nov. was carefully examined, but only two possible stomata were detected on an area of more than 150 mm². Therefore, there might be very few or no stomata on the sporophylls of *D. baculiformis* sp. nov. Meanwhile, a number of fragments of *Y. wudensis* sp. nov. were examined, but unfortunately, no stomata were detected over an area of more than 300 mm² of lamina. It could not be determined if the specimen represents the adaxial or abaxial surface of the lamina. It is unfortunate that the observed cell pattern of the sporophylls of *D. baculiformis* sp. nov. and the lamina of *Y. wudensis* sp. nov. did not show stomata, which might have aided in determining whether the two form species belong to the same natural species.

Acknowledgments

This study was funded by the National Natural Science Foundation of China (projects 40102002, 40321202) and KZCX2-SW-130, Chinese Academy of Sciences. We would like to acknowledge the State Key Laboratory of Paleobiol-

ogy and the Nanjing Institute of Geology and Palaeontology for the use of LEO 1530VP, JSM-6300, and Leica DC300 to make SEM and stereomicroscope observations. We thank

the reviewer for providing information on *Discinites* strobili in the Czech Republic and Barbara Pfefferkorn for editorial help.
