Optimal Value and Growth Tilts in Long-Horizon Portfolios

Abstract
We develop an analytical solution to the dynamic portfolio choice problem of an investor with power utility defined over wealth at a finite horizon, who faces a time-varying investment opportunity set, parameterized using a flexible vector autoregression. We apply this framework to study the horizon effects in the allocations of equity-only investors, who hold a mix of value and growth indices, and a more general investor, who also has access to Treasury bills and bonds. We find that the mean allocation of equity-only investors is heavily tilted towards value stocks at short-horizons, but the magnitude of this tilt declines dramatically with the investment horizon, implying that growth is less risky than value at long horizons. Investors with access to bills and bonds exhibit similar behavior, when value and growth tilts are computed relative to the total equity allocation of the portfolio. However, after accounting for the propensity of these investors to increase their total equity allocation as the horizon increases, the mean value tilt of the optimal allocation is shown to be positive and stable across time.

Optimal Value and Growth Tilts in Long-Horizon Portfolios

Abstract

We develop an analytical solution to the dynamic portfolio choice problem of an investor with power utility defined over wealth at a finite horizon, who faces a time-varying investment opportunity set, parameterized using a flexible vector autoregression. We apply this framework to study the horizon effects in the allocations of equity-only investors, who hold a mix of value and growth indices, and a more general investor, who also has access to Treasury bills and bonds. We find that the mean allocation of equity-only investors is heavily tilted towards value stocks at short-horizons, but the magnitude of this tilt declines dramatically with the investment horizon, implying that growth is less risky than value at long horizons. Investors with access to bills and bonds exhibit similar behavior, when value and growth tilts are computed relative to the total equity allocation of the portfolio. However, after accounting for the propensity of these investors to increase their total equity allocation as the horizon increases, the mean value tilt of the optimal allocation is shown to be positive and stable across time.
1 Introduction

Long-term investors seek portfolio strategies that optimally trade off risk and reward, not in the immediate future, but over the long term. Consider for example a long-term investor who cares only about the distribution of her wealth at some given future date. Today, at time $t$, the investor picks a portfolio to maximize the expected utility of wealth at time $t + K$, where $K$ is the investment horizon. If the portfolio must be chosen once and for all, with no possibility of rebalancing between $t$ and $t + K$, then this is a static portfolio choice problem of the sort studied by Markowitz (1952). The solution depends on the risk properties of returns measured over $K$ periods, but given these risk properties the portfolio choice problem is straightforward.\footnote{Campbell and Viceira (2005) provide an accessible discussion of the risk properties of US stocks, bonds, and Treasury bills at long horizons and the implications for optimal long-term buy-and-hold portfolios.}

When investment opportunities (i.e. risk premia, interest rates, inflation, etc.) are time-varying, however, it is unrealistic to assume that long-term investors will adopt this “invest and forget” strategy. Instead, rather than find a single optimal portfolio, the investor must specify an entire optimal dynamic portfolio strategy or contingent plan that delineates how to adjust asset allocations in response to changes in investment opportunities. Solving for this contingent plan is a challenging problem. Samuelson (1969) and Merton (1969, 1971, 1973) showed how to use dynamic programming to characterize the solution to this type of problem, but did not derive closed-form solutions except for the special cases where the long-term strategy is identical to a sequence of optimal short-term strategies.

In recent years financial economists have explored many alternative solution methods for the long-term portfolio choice problem with rebalancing. Exact analytical solutions have been discovered for a variety of special cases (e.g. Kim and Omberg 1996, Brennan and Xia 2002, Wachter 2002, Chacko and Viceira 2005, Liu 2007), but these often fail to capture all the dimensions of variation in the investment opportunity set that appear to be relevant empirically. In particular, with the exception of Liu (2007), these models typically do not allow both the real interest rate and risk premia to vary over time. Numerical methods have also been developed for this type of problem and range from discretizing the state space (e.g. Balduzzi and Lynch 1999, Barberis 2000, Lynch 2001) to numerically solving the PDE characterizing the dynamic program (e.g. Brennan, Schwartz, and Lagnado 1997, 1999). Although numerical methods can, in principle, handle arbitrarily complex model setups with realistic return distributions and portfolio constraints, in practice it has proven difficult to use these methods in problems with more than a few state variables. Finally, there are approximate analytical methods that deliver solutions that are accurate in the neighborhood of special cases for which closed-form results are available. Campbell and Viceira (1999, 2001, 2002) develop this approach for the case of an infinitely lived investor who derives utility from consumption rather than wealth. Their method is accurate provided the investor’s consumption-wealth ratio is not too variable. Campbell, Chan, and Viceira (2003, CCV henceforth) apply the method to a
problem with multiple risky assets and allow both the real interest rate and risk premia to change over time.

This paper makes several contributions to the portfolio choice literature. First, we provide an analytical recursive solution to the dynamic portfolio choice problem of an investor whose utility is defined over wealth at a future date, in an environment with time-varying investment opportunities. The variation in risk premia, inflation, interest rates and the state variables that drive them is parsimoniously captured using a VAR(1) model. By using the vector autoregressive framework we are able to handle a large number of investable assets and state variables, providing a convenient laboratory for the examination of horizon effects in portfolio choice. Our recursive solution is based on the Campbell-Viceira approximation to the log-portfolio return, and consequently—like the approximation itself—is exact in continuous time. In fact, our solution can be interpreted as a discretized version of the exact solution obtained by Liu (2007) in continuous time. Specifically, Liu (2007) shows that—when asset returns follow quadratic processes and investors’ preferences are described by isoelastic utility—the dynamic portfolio choice problem reduces to a system of Riccati equations, which can be solved analytically using Radon’s Lemma.

Second, we elucidate why log utility represents a knife-edge case in which dynamic asset pricing models produce the same predictions as static asset pricing models even if investment opportunities are time varying. The intuition we provide is based on the differing behavior of geometric mean returns and arithmetic mean returns at long horizons. We show that expected per period long-horizon gross asset returns—or arithmetic mean returns—are, in general, a function of investment horizon, while expected per period long-horizon log asset returns—or geometric mean returns—are always independent of investment horizon. Because log utility investors seek to maximize the mean log return on their wealth, horizon considerations are not relevant to them, leading them to behave like investors with a one-period horizon.

Finally, we apply our method to study the optimal growth and value tilts in the portfolios of long-horizon investors. Most empirically motivated studies of optimal dynamic portfolio choice problems focus on the choice between a well-diversified portfolio of equities representing the market, and other assets such as cash and long-term bonds. These studies constrain investors who want exposure to equities to hold the aggregate stock market portfolio. However, in an environment of changing expected returns, it is plausible that the composition of an investor’s optimal equity portfolio will differ from the market portfolio. Merton (1969, 1971, 1973) shows that long-horizon risk averse investors optimally tilt their portfolios toward those assets whose realized returns are most negatively correlated with unexpected changes in expected returns, because they help hedge their wealth—and consumption—against a deterioration in investment opportunities. In fact, recent work by Campbell and Vuolteenaho (2004) and others, has documented that the risk characteristics of value and growth stocks differ precisely along these lines, motivating our interest in understanding value and growth tilts in long-horizon portfolios.

3 In concurrent work, Sorensen and Trolle (2009) derive a solution similar to ours, which they use to study dynamic asset allocation with latent state variables.
Campbell and Vuolteenaho (2004) find that the conditional correlation of returns with variables that proxy for time variation in aggregate stock market discount rates is larger for growth stocks than for value stocks, while the conditional correlation of returns with changes in aggregate stock market cash flows is larger for value stocks than for growth stocks. They argue that this should make value stocks riskier than growth stocks from the perspective of a long-horizon risk averse investor, because empirically changes in aggregate stock discount rates are transitory, while changes in aggregate expected cash flows are largely permanent. We verify this prediction in the context of our portfolio choice framework by showing that a risk-averse investor, constrained to hold only value and growth stocks, decreases his allocation to value as his investment horizon increases.

The importance of understanding the optimal value and growth tilts in the portfolios of long-horizon investors is further underscored by the composition of the retail mutual fund universe. According to the CRSP Mutual Fund Database, as of the second quarter of 2005, there were 3797 diversified, domestic equity mutual funds with roughly 2.32 trillion dollars in assets under management. Of these funds, 1748 (46%) were classified by CRSP as dedicated growth funds and 1219 (32%) were classified as dedicated value funds, with the remaining 830 (22%) being classified as blend funds. Funds with a dedicated value or growth tilt accounted for 76% of total assets under management (36% growth and 42% value). Thus value and growth tilts are the norm, rather than the exception, in the mutual fund industry that serves the investment needs of most retail investors.

We first apply our dynamic portfolio choice framework to the study the horizon effects in the allocations of equity-only investors, who hold a mix of value and growth indices, and a more general investor, who also has access to Treasury bills and bonds. Our interest in the equity-only investor is motivated by the fact that this investor type is implicit in representative-agent general equilibrium models in which equities are typically the only asset in positive net supply and variation in investment opportunities is specified exogenously. To this end, we model investment opportunities using a vector autoregressive model that includes the returns on growth and value stocks, as well as variables that proxy for expected aggregate stock returns. We then explore the robustness of these results to the inclusion of other assets, such as T-bills and long-term bonds, in the investment opportunity set while allowing for temporal variation in expected bond excess returns, real interest rates, and inflation. We find that the mean-allocation of equity-only investors is heavily tilted towards value stocks at short-horizons, but the magnitude of this tilt declines dramatically with the investment horizon, implying that growth is less risky than value at long horizons. Investors with access to bills and bonds exhibit similar behavior, when value and growth tilts are computed relative to the total equity allocation of the portfolio. However, after accounting for the propensity of these investors to increase their total equity allocation as the horizon increases, the mean value tilt of the optimal allocation is shown to be positive and stable across time.

---

4 We classify a mutual fund as an *equity* fund if its holdings of cash and common equities account for over 90% of the portfolio value. *Diversified* equity funds exclude sector funds with total net assets under management of 191 billion dollars.
Our empirical application is closest to Lynch’s (2001) numerical exploration of value and size tilts in the portfolios of a long-horizon power utility investor in the presence of a time-varying investment opportunity set. In his paper, the variation in investment opportunities is described by the dividend yield on the aggregate stock market and the spread between the long and the short nominal interest rates. Our results effectively represent the analytical counterpart to his analysis, which was based on numerical dynamic programming methods. The convenience of our analytical solution, however, allows us to examine a broader range asset classes and a richer specification of the state vector. Furthermore, we document that his conclusions regarding the horizon dependence of value and growth tilts are sensitive to the methodology applied in their computation.

The organization of the paper is as follows. Section 2 specifies investment opportunities and investor’s preferences, and it states the intertemporal optimization problem. Section 3 solves the dynamic portfolio model and discusses the solution. Section 4 applies our method to the empirically relevant problem of constructing an optimal long-term portfolio of value stocks, growth stocks, bonds, and bills given historically estimated return processes. Finally, Section 5 concludes. The Appendix provides a detailed derivation of all the analytical results in the paper.

2 Investment opportunities and investors

We start by outlining our assumptions about the dynamics of the available investment opportunities. We then turn to an analysis of the effect of intertemporal variation in the investment opportunity set on the moments of risky asset returns at long-horizons, and finally, we formalize the investor’s optimization problem.

2.1 Investment opportunities

We consider an economy with multiple assets available for investment, where expected returns and interest rates are time varying. We assume that asset returns and the state variables that characterize time variation in expected returns and interest rates are jointly determined by a first-order linear vector autoregression, or VAR(1):

\[ z_{t+1} = \Phi_0 + \Phi_1 z_t + v_{t+1}. \]

Here \( z_{t+1} \) denotes an \((m \times 1)\) column vector whose elements are the returns on all assets under consideration, and the values of the state variables at time \((t + 1)\). \( \Phi_0 \) is a vector of intercepts, and \( \Phi_1 \) is a square matrix. In another related paper, Brennan and Xia (2001), explore the value spread as a “data anomaly” whose existence as a real phenomenon is assessed by a Bayesian investor. Unlike our paper, however, they ignore time variation in investment opportunities.
that stacks together the slope coefficients. Finally, \( v_{t+1} \) is a vector of zero-mean shocks to the realizations of returns and return forecasting variables. We assume these shocks are homoskedastic and normally distributed:

\[
v_{t+1} \sim i.i.d. \mathcal{N}(0, \Sigma_v). \tag{2}
\]

For convenience for our subsequent portfolio analysis, we write the vector \( z_{t+1} \) as

\[
z_{t+1} \equiv \begin{bmatrix} r_{1,t+1} \\ r_{t+1} - r_{1,t+1} \mathbf{1} \\ s_{t+1} \end{bmatrix} \equiv \begin{bmatrix} r_{1,t+1} \\ \mathbf{x}_{t+1} \\ s_{t+1} \end{bmatrix}, \tag{3}
\]

where \( r_{1,t+1} \) denotes the log real return on the asset that we use as a benchmark in excess return computations, \( \mathbf{x}_{t+1} \) is a vector of log excess returns on all other assets with respect to the benchmark, and \( s_{t+1} \) is a vector with the realizations of the state variables. For future reference, we assume that there are \( n+1 \) assets, and \( m - n - 1 \) state variables.

Consistent with our representation of \( z_{t+1} \) in (3), we can write \( \Sigma_v \) as

\[
\Sigma_v \equiv \text{Var}_t(v_{t+1}) = \begin{bmatrix} \sigma_1^2 & \sigma_{1x} & \sigma_{1s} \\ \sigma_{1x} & \Sigma_{xx} & \Sigma_{xs} \\ \sigma_{1s} & \Sigma_{xs} & \Sigma_s \end{bmatrix},
\]

where the elements on the main diagonal are the variance of the real return on the benchmark asset (\( \sigma_1^2 \)), the variance-covariance matrix of unexpected excess returns (\( \Sigma_{xx} \)), and the variance-covariance matrix of the shocks to the state variables (\( \Sigma_s \)). The off-diagonal elements are the covariances of the real return on the benchmark assets with excess returns on all other assets and with shocks to the state variables (\( \sigma_{1x} \) and \( \sigma_{1s} \)), and the covariances of excess returns with shocks to the state variables (\( \Sigma_{xs} \)).

### 2.2 Long-horizon asset return moments

Despite the seemingly restrictive assumption of homoskedasticity of the VAR shocks, the vector autoregressive specification is able to capture a rich set of dynamics in the moments of long-horizon asset returns. In particular, at horizons exceeding one period, asset return predictability generates variation in per period risk and expected gross returns (or arithmetic mean returns) across investment horizons, regardless of whether the conditional second moments of the VAR shocks are constant over time or not. We emphasize

---

6While the simplifying assumption of time invariant risk is perhaps not empirically plausible, it is nonetheless relatively harmless given our focus on long-term portfolio choice decisions. Using a realistically calibrated model of stock return volatility, Chacko and Viceira (2005) argue that the persistence and volatility of risk are not large enough to have a sizable impact on the portfolio decisions of long-term investors, relative to the portfolio decisions of short-horizon investors.
these implications of asset return predictability here, because they are useful in understanding horizon effects on portfolio choice shown in Section 3.

Consider the conditional variance of $K$-period log excess returns,

$$\text{Var}_t [r_{t \rightarrow t+K} - r_{1, t \rightarrow t+K}] \equiv \Sigma^{(K)}_{xx},$$

where we have defined $r_{t \rightarrow t+K} = \sum_{i=1}^{K} r_{t+i}$, and $r_{1, t \rightarrow t+K} = \sum_{i=1}^{K} r_{1, t+i}$. Of course, $\Sigma^{(1)}_{xx}$ is simply the conditional variance of one-period excess returns, $\Sigma_{xx}$.

We show in the Appendix that when expected returns are constant—that is, when the slope coefficients in the equations for excess returns in the VAR(1) model are all zero—$\Sigma^{(K)}_{xx}/K = \Sigma_{xx}$ at all horizons. By contrast, return predictability implies that $\Sigma^{(K)}_{xx}$ will generally be different from $\Sigma_{xx}$, thus generating a term structure of risk (Campbell and Viceira 2005). Similar considerations apply to the conditional variance of $K$-period returns on the benchmark asset, which we denote by $(\sigma_{1x})^2$, and the conditional covariance of excess returns with the return on the benchmark asset, which we denote by $\sigma_{1x}$.

Return predictability also generates a term structure of expected gross returns. To see this, note that under (1)-(2), the log of the unconditional mean gross excess return per period at horizon $K$ (or the log of the population arithmetic mean return) is related to the unconditional mean log excess return per period at horizon $K$ (the population geometric mean return) as follows:7

$$\frac{1}{K} \log \mathbb{E} \left[ \exp(r_{t \rightarrow t+K} - r_{1, t \rightarrow t+K}) \right] = \mathbb{E} \left[ r_{t+1} - r_{1, t+1} \right] + \frac{1}{2K} \text{diag} \left( \Sigma^{(K)}_{xx} \right) + \frac{1}{2K} \text{Var} \left[ \mathbb{E}_t \left[ r_{t \rightarrow t+K} - r_{1, t \rightarrow t+K} \right] \right]$$

Equation (4) implies that the arithmetic mean return is horizon dependent, whereas the geometric mean return is horizon independent. The dependence of the arithmetic mean return on horizon operates through the variance terms, which do not grow linearly with horizon unless returns are not predictable. In the special case of no return predictability, we have that $\Sigma^{(K)}_{xx} = K \Sigma_{xx}$ and $\text{Var} \left[ \mathbb{E}_t \left[ r_{t \rightarrow t+K} - r_{1, t \rightarrow t+K} \right] \right] = 0$.8

---

7 This equation follows immediately from applying a standard variance decomposition result:

$$\log \mathbb{E} \left[ \exp(r_{t \rightarrow t+K} - r_{1, t \rightarrow t+K}) \right] = \mathbb{E} \left[ r_{t \rightarrow t+K} - r_{1, t \rightarrow t+K} \right] + \frac{1}{2} \left( \mathbb{E} [\text{Var}_t \left[ r_{t \rightarrow t+K} - r_{1, t \rightarrow t+K} \right]] + \text{Var} \left[ \mathbb{E}_t \left[ r_{t \rightarrow t+K} - r_{1, t \rightarrow t+K} \right] \right] \right)$$

8 More generally $\text{Var} \left[ \mathbb{E}_t \left[ r_{t \rightarrow t+K} - r_{1, t \rightarrow t+K} \right] \right]$ equals the elements in the diagonal of

$$\left( \sum_{j=1}^{K} \Phi_1 \right) \text{Var}[z_t] \left( \sum_{j=1}^{K} \Phi_1 \right)'$$

corresponding to log excess returns.
Equation (4) gives us strong intuition about the set of investors for whom horizon effects are important. It suggests that investment horizon considerations will be irrelevant to investors who care only about maximizing the geometric mean return on their wealth, while they will be highly relevant to investors for whom the criterion for making portfolio decisions is the arithmetic mean return on their wealth.

Figure 1 gives an empirical illustration of horizon effects on expected returns. This figure plots the annualized geometric mean return (dash-dot line) and annualized arithmetic mean return (solid line) on U.S. stocks and a constant maturity 5-year Treasury bond as a function of investment horizon. The figure considers investment horizons between 1 month and 300 months (or 25 years). The geometric average return per period of course does not change with the horizon, but the arithmetic mean return per period does change significantly. For U.S. equities, it goes from about 5.3% per year at a 1-quarter horizon to about 4.9% at a 25-year horizon. For U.S. bonds, it decreases from about 1.8% per year to about 1.7% per year. The declining average arithmetic return is the direct result of a pattern of decreasing volatility per period of stock and bond returns across investment horizons, which is more pronounced for stocks than for bonds (Campbell and Viceira, 2005).

2.3 Investor’s Problem

We consider an investor with initial wealth $W_t$ at time $t$ who chooses a portfolio strategy that maximizes the expected utility of wealth $K$ periods ahead. The investor has isoelastic preferences with a constant coefficient of relative risk aversion, $\gamma$, and consumes the accumulated wealth at the terminal date, $t + K$.

Formally, the investor chooses the sequence of portfolio weights $\alpha_{t+K-\tau}$ between time $t$ and $(t+K-1)$ such that

$$\left\{\alpha_{t+K-\tau}\right\}_{\tau=1}^{\tau=K} = \arg \max \mathbb{E}_t \left[ \frac{1}{1 - \gamma} W_{t+K}^{1-\gamma} \right],$$

when $\gamma \neq 1$, and

$$\left\{\alpha_{t+K-\tau}\right\}_{\tau=1}^{\tau=K} = \arg \max \mathbb{E}_t \left[ \log (W_{t+K}) \right].$$

when $\gamma = 1$. Note that we index the sequence of portfolio weight vectors by the time at which they are chosen (subscript) and the time-remaining to the horizon (superscript $\tau$).

Investor’s wealth evolves over time as:

$$W_{t+1} = W_t (1 + R_{p,t+1}),$$

$^9$This figure is based on a VAR(1) system estimated using postwar monthly data. The VAR includes the same state variables as the VAR we use in our empirical application. See Section 5 for details.
where \((1 + R_{p,t+1})\), the gross return on wealth, is given by

\[
1 + R_{p,t+1} = \sum_{j=1}^{n} \alpha_{j,t} (R_{j,t+1} - R_{1,t+1}) + (1 + R_{1,t+1})
\]

\[
= \alpha' (R_{t+1} - R_{1,t+1}) + (1 + R_{1,t+1}),
\]

(7)

which is a linear function of the vector of portfolio weights at time \(t\).

Equation (6) implies that the terminal wealth, \(W_{t+K}\), is equal to the initial wealth, \(W_t\), multiplied by the cumulative \(K\)-period gross return on wealth, which itself is a function of the sequence of decision variables \(\{\alpha_{t+i-1}^{(K-i+1)}\}_{i=1}^{K}\):

\[
W_{t+K} = W_t \cdot \prod_{i=1}^{K} (1 + R_{p,t+i} (\alpha_{t+i-1}^{(K-i+1)})).
\]

The preference structure in the model implies that the investor always chooses a portfolio policy such that \((1 + R_{p,t+i}) > 0\).\(^{10}\) Thus, along the optimal path,

\[
W_{t+K} = W_t \cdot \exp \{r_{p,t-t+K}\},
\]

(8)

where \(r_{p,t-t+K} = \sum_{i=1}^{K} r_{p,t+i}\) is the \(K\)-period log return on wealth between times \(t\) and \(t + K\).

Using (8) we can rewrite the objective function (5) as:

\[
\{\alpha_{t+K-\tau}^{(\tau)}\}_{\tau=1}^{\tau=K} = \arg\max_{\tau=K} \frac{1}{1 - \gamma} E_t [\exp \{(1 - \gamma) r_{p,t-t+K}\}],
\]

(9)

when \(\gamma \neq 1\), and

\[
\{\alpha_{t+K-\tau}^{(\tau)}\}_{\tau=1}^{\tau=K} = \arg\max E_t [r_{p,t-t+K}].
\]

(10)

when \(\gamma = 1\). For simplicity we have dropped the scaling factors \(W_t^{1-\gamma}\) and \(\log(W_t)\) from the objective functions (9) and (10), which are irrelevant for optimality conditions.

Equation (9) says that a power utility investor with \(\gamma \neq 1\) seeks to maximize a power function of the expected long-horizon gross return on wealth. By contrast, equation (10) says that a log utility investor seeks to maximize the expected long-horizon log return on wealth. Section 2.2 shows that expected long-horizon gross returns per period are in general a function of investment horizon, while expected long-horizon log returns per period are not. Since the first order conditions implied by these objective functions are invariant to a change of scale, we can already say, before formally deriving the optimal portfolio policies for each type of investor, that the optimal portfolio policy for investors with \(\gamma \neq 1\) will be a function of

\(^{10}\)To see this, note that a zero one-period gross return on wealth at any date implies zero wealth and consumption at time \(t + K\), which in turn implies that marginal utility of consumption approaches infinity. This is a state of the world the investor will surely avoid.
investment horizon, while the optimal portfolio policy for log utility investors will not.

Finally, following CCV (2003) we approximate the log return on the wealth portfolio (7) as:

\[
r_{p,t+1} \approx r_{1,t+1} + \alpha_t^i (r_{t+i} - r_{1,t+1}) + \frac{1}{2} \alpha_t^i \left( \sigma_x^2 - \Sigma_x \alpha_t \right),
\]

where \( \sigma_x^2 \equiv \text{diag}(\Sigma_{xx}) \) is the vector consisting of the diagonal elements of \( \Sigma_{xx} \), the variances of log excess returns. Equation (11) is an approximation which becomes increasingly accurate as the frequency of portfolio rebalancing increases, and it is exact in the continuous time limit.

3 A general recursive solution

We solve for the optimal dynamic rebalancing strategy by applying a standard backwards recursion argument. We first derive the portfolio rule in the last period (the base case for the policy function recursion) and the associated value function (the base case for the value function recursion). We then solve the problem for the period preceding the last portfolio choice date as a function of the value and policy function coefficients from the terminal period. This enables us to isolate the recursive relationship linking the policy function and value function recursions for two adjacent periods. By iterating this relationship we arrive at the solution to the general multi-period portfolio choice problem with dynamic rebalancing.

Our solution is a discretized version of the solution in Liu (2007) for the case in which the vector of state variables follows a multivariate Ornstein-Uhlenbeck process—see Definition 1.2 in Liu (2007)—and there is no instantaneously riskless asset. As such, our solution possesses a variety of attractive features. First, it flexibly accommodates any number of risky assets and state variables. Second, it is exact in the limit when the investor can rebalance the portfolio continuously, since the loglinear approximation (11) is exact in continuous time. And lastly, in the special cases when there is only one period remaining or returns are not predictable, our solution simplifies to the well known myopic portfolio choice rule.

3.1 Optimal portfolio policy and value functions with one period remaining

Equation (9) implies that the objective for an investor with one period remaining to the terminal date, \( t + K \), is to choose \( \alpha_{t+K-1}^{(1)} \) such that:

\[
\alpha_{t+K-1}^{(1)} = \arg \max \frac{1}{1-\gamma} E_{t+K-1} \left[ \exp \left\{ (1 - \gamma) r_{p,t+K} \right\} \right].
\]

(12)
Under the distributional assumption (2) and the approximation to the portfolio return (11), \( r_{p,t+K} \) is conditionally lognormal allowing us to re-express the expectation in equation (12) as:

\[
E_{t+K-1} \left\{ \exp \left\{ (1 - \gamma) r_{p,t+K} \right\} \right\} = \exp \left\{ (1 - \gamma) E_{t+K-1} \left[ r_{p,t+K} \right] + \frac{1}{2} (1 - \gamma)^2 \text{Var}_{t+K-1} \left[ r_{p,t+K} \right] \right\}.
\] (13)

Substituting (13) into (12) and solving for the optimal portfolio weight vector we obtain the following solution:

\[
\alpha^{(1)}_{t+K-1} = \frac{1}{\gamma} \Sigma_{xx}^{-1} \left( E_{t+K-1} \left[ r_{t+K} - r_{1,t+K} \right] + \frac{1}{2} \sigma_x^2 + (1 - \gamma) \sigma_{1x} \right),
\] (14)

where

\[
E_{t+K-1} \left[ r_{t+K} - r_{0,t+K} \right] = H_x \left( \Phi_0 + \Phi_1 z_{t+K-1} \right),
\] (15)

and \( H_x \) is a matrix operator that selects the rows corresponding to the vector of excess returns \( x \) from the target matrix. Thus the solution (14) implicitly defines an affine function of the state vector \( z_{t+K-1} \).

Equation (14) is the well-known “myopic” or one-period mean-variance efficient portfolio rule. The optimal myopic portfolio (14) combines the tangency portfolio and the global minimum variance portfolio of the mean-variance efficient frontier generated by one-period expected returns and the conditional variance-covariance matrix of one-period returns. The tangency portfolio is:

\[
\Sigma_{xx}^{-1} E_{t+K-1} \left[ r_{t+K} - r_{1,t+K} \right] + \frac{1}{2} \sigma_x^2.
\] (16)

This portfolio depends on expected returns and the variance-covariance matrix of returns. In our model, expected returns are time-varying, causing this portfolio to change with the investment opportunities. The global minimum variance (GMV) portfolio is

\[
-\Sigma_{xx}^{-1} \sigma_{1x},
\] (17)

and depends only on the variance-covariance structure of returns. Our assumption of constant variances and covariances implies that the single-period GMV portfolio does not change with investment opportunities.

Investors combine these two portfolios using weights \( 1/\gamma \) and \( (1 - 1/\gamma) \), respectively. Log utility investors (investors with unit coefficient of relative risk aversion \( \gamma \) ) hold only the tangency portfolio, while highly risk averse investors (investors for whom \( \gamma \to \infty \) ) hold only the GMV portfolio. Other investors hold a mixture of both.

**Value function**

The conditional lognormality of \( r_{p,t+K} \) and equation (13) indicate that the value function at time \( (t + K - 1) \) depends on the expected log return on wealth and its variance. Substitution of the optimal portfolio rule (14) into the equation for the log return on wealth (11) leads to expressions for the expected
log return on wealth and its variance which are both quadratic functions of the \( z_{t+K-1} \) vector. This is intuitive, since the expected log return on wealth depends on the product of \( \alpha_{t+K-1}^{(1)} \) and the expected return on wealth, both of which are linear in \( z_{t+K-1} \); similarly, the conditional variance of the log return on wealth depends quadratically on \( \alpha_{t+K-1}^{(1)} \), which is itself a linear function of \( z_{t+K-1} \). Therefore, the expectation in the value function at time \( (t+K-1) \) is itself an exponential quadratic polynomial of \( z_{t+K-1} \):

\[
E_{t+K-1} \left[ \exp \left\{ (1 - \gamma) r_{p,t+K} \right\} \right] \propto \exp \left\{ (1 - \gamma) \left( B_0^{(1)} + B_1^{(1)} z_{t+K-1} + z_{t+K-1}' B_2^{(1)} z_{t+K-1} \right) \right\} \tag{18}
\]

where \( B_0^{(1)} \), \( B_1^{(1)} \), and \( B_2^{(1)} \) are given in the Appendix.

### 3.2 Optimal portfolio policy and value functions with two periods remaining

We now proceed to compute the optimal portfolio policy and the value function at time \( (t + K - 2) \). When the remaining horizon is two periods, the investor’s objective function is

\[
\max_{\alpha_{t+K-2}^{(2)} \alpha_{t+K-1}^{(1)}} \frac{1}{1 - \gamma} E_{t+K-2} \left[ \exp \left\{ (1 - \gamma) \left( r_{p,t+K-1} + r_{p,t+K} \right) \right\} \right] \tag{19}
\]

which, using the law of iterated expectations and equation (18), we can further rewrite as

\[
\max_{\alpha_{t+K-2}^{(2)}} \frac{1}{1 - \gamma} E_{t+K-2} \left[ \exp \left\{ (1 - \gamma) \left( r_{p,t+K-1} + B_1^{(1)} z_{t+K-1} + z_{t+K-1}' B_2^{(1)} z_{t+K-1} \right) \right\} \right]. \tag{20}
\]

In order to compute the optimal portfolio policy and the value function at \( (t + K - 2) \), we need to evaluate the expectation (20). Note that the last two terms inside the expectation define an affine-quadratic function of \( z_{t+K-1} \), and that equation (11) implies that \( r_{p,t+K-1} \) is an affine function of \( z_{t+K-1} \). Thus the term inside the expectation is an exponential quadratic polynomial function of the vector of state variables \( z_{t+K-1} \). We can evaluate this expectation in closed form using standard results on the expectation of an exponential quadratic polynomial of normal variables. The Appendix provides an analytical expression for (20), and some additional simplifications applicable in the continuous-time limit.

The analytical evaluation of the expectation (20) results in an objective function\(^{11}\) whose first order condition implies an optimal portfolio policy which, similar to the optimal one-period portfolio policy, is also an affine function of the state vector \( z_{t+K-2} \). It is important however to note that the coefficients of this function will, in general, be different from the coefficients of the state vector \( z_{t+K-1} \) in the one-period solution. They differ in qualitatively important ways that capture the fact that the optimal portfolio rule

\(^{11}\)The objective function is itself an exponential quadratic polynomial function of \( z_{t+K-2} \) whose coefficients depend on \( \alpha_{t+K-2}^{(2)} \), the decision variable. Viewed as a function of \( \alpha_{t+K-2}^{(2)} \), the objective function is also an exponential quadratic polynomial function of \( \alpha_{t+K-2}^{(2)} \).
is not necessarily myopic when the remaining investment horizon is longer than one period—and the agent anticipates further opportunities for portfolio rebalancing in the face of changing investment opportunities. We defer the discussion of these differences until we present the general solution at any remaining horizon \( \tau \) in the next section.

**Value function**

Substitution of the optimal portfolio policy \( \alpha_{t+K-2}^{(2)} \) back into the objective function leads to a value function at \((t+K-2)\) which has the same functional form as the value function \((18)\) at \((t+K-1)\), but with coefficients \(B_0^{(2)}, B_1^{(2)},\) and \(B_2^{(2)}\) that will generally be different from the coefficients of the one-period value function. The Appendix provides expressions for these coefficients.

### 3.3 General recursive solution and its properties

The results for the cases with one \((\tau = 1)\) and two \((\tau = 2)\) periods remaining to the terminal date implicitly define the recursion generating the optimal portfolio policy for an arbitrary horizon \( \tau \). The solution to the one-period problem represents the base case for the recursive solution, and the solution to the two-period problem provides the link between the policy and value functions in adjacent time periods.

In the Appendix, we show that with \( \tau \) periods remaining to the terminal date, the optimal portfolio rule is given by

\[
\alpha_{t+K-\tau}^{(\tau)} = \frac{1}{\gamma} \Sigma_{xx}^{-1} \left( E_{t+K-\tau} [r_{t+K-\tau+1} - r_{t+K-\tau+1}] + \frac{1}{2} \sigma_x^2 + (1 - \gamma) \sigma_{1x} \right) - \left(1 - \frac{1}{\gamma}\right) \Sigma_{xx}^{-1} \Sigma_x \left( B_1^{(\tau-1)} + B_2^{(\tau-1)} \right) E_{t+K-\tau} [z_{t+K-\tau+1}],
\]

where \( \Sigma_x = [\sigma_{1x} \Sigma_{xx} \Sigma'_{xx}] \) and \( B_1^{(\tau-1)}, B_2^{(\tau-1)}, \) and \( B_2^{(\tau-1)} \) are functions of the remaining investment horizon \( \tau \), the coefficient of relative risk aversion \( \gamma \), and the coefficients of the VAR system given in the Appendix.

Equation (21) provides a fully analytical solution to the intertemporal portfolio choice problem of Section 2. It shows that optimal portfolio demand is the sum of two components or portfolios. The first component, given by the first line in the equation, is identical to the one-period myopic portfolio demand (14). The second component, given by the second line in the equation, reflects an additional intertemporal hedging portfolio demand for risky assets (Merton 1969, 1971, 1973).

Equation (21) shows that the myopic component of total portfolio demand is independent of investment horizon \( \tau \). It also shows that this component of total portfolio demand is the total optimal portfolio demand for log utility investors—i.e., investors with \( \gamma = 1 \). This confirms our intuition in Section 2.3 that horizon
considerations are irrelevant for log utility investors, since they seek to maximize the long-horizon log return on wealth per period, which is independent of horizon.

The intertemporal hedging component of portfolio demand combines two elements: The first element, $\Sigma_{xx}^{-1}\Sigma_{xz}$, captures the ability of assets to hedge changes in investment opportunities through their instantaneous correlation with the vector of state variables. The second element, given by $(1 - 1/\gamma)$ and the terms post-multiplying $\Sigma_{xx}^{-1}\Sigma_{xz}$ in (21), captures the effect of changes in investment opportunities on the investor's marginal utility of wealth.\(^{12}\) Equation (21) shows that this element is both state-dependent, through $E_{t+k-\tau}[z_{t+k-\tau+1}]$, and horizon-dependent, through $B_1^{(\tau-1)}, B_2^{(\tau-1)},$ and $B_2^{(\tau-1)}$.

Therefore, it is through the intertemporal hedging component that investment horizon affects optimal portfolio demand. Equation (14) shows that this component is always zero when $\tau = 1$, that is, when investors have only one period to go before liquidating their assets and consuming their wealth, but it is not necessarily zero when $\tau > 1$. Investors with multi-period horizons are exposed to shocks affecting not only their realized wealth, but also the future productivity of their wealth. They choose portfolios which respond optimally not only to prevailing market conditions (myopic demand), but also to future changes in investment opportunities. In particular, risk averse investors might want to tilt their portfolios toward assets that protect their wealth from adverse changes in investment opportunities (Merton 1969, 1971, 1973).

Re-expressing the expectations in equation (21) in terms of $z_{t+k-\tau}$ shows that each component of total portfolio demand is an affine function of the vector of state variables $z_{t+k-\tau}$. Thus we can rewrite total portfolio demand $\sigma_{t+k-\tau}$ itself as an affine function of the vector of state variables:

$$\sigma_{t+k-\tau} = A_0^{(\tau)} + A_1^{(\tau)} z_{t+k-\tau},$$

where the expressions for $A_0^{(\tau)}$ and $A_1^{(\tau)}$ can be deduced straightforwardly from (21). The dynamic consistency of the policy function ensures that the coefficient matrices, $A_0^{(\tau)}$ and $A_1^{(\tau)}$, depend on the time remaining to the terminal horizon date, but are independent of time itself. Consequently, we index these coefficients by the time remaining to the consumption date.

The optimal dynamic portfolio policy (21) converges to well-known solutions in certain limiting cases. We show in the Appendix that when investors have log utility ($\gamma \to 1$), or when investment opportunities are constant ($H_0 \Phi_1 = 0$), we have $A_0^{(\tau)} = A_0^{(1)}$ and $A_1^{(\tau)} = A_1^{(1)}$ for all $\tau$. Thus the optimal dynamic policy (21) reduces to the myopic solution at all horizons.

We also show in the Appendix that as we consider increasingly risk averse investors (i.e., as $\gamma \to \infty$), the optimal portfolio policy becomes decoupled from the intercept vector, $\Phi_0$, of the VAR(1). That is,
the least-risky portfolio from the perspective of a long-horizon investor, who can rebalance dynamically, is independent of the vector of unconditional mean returns. This portfolio converges to the one-period GMV when investment opportunities are constant.

**Value function**

The value function with \( \tau \) periods remaining continues to be an exponential quadratic function of the state vector:

\[
\max_{\alpha} \frac{1}{1 - \gamma} \mathbb{E}_{t+K-\tau}\left[ \exp \left\{ (1 - \gamma) \sum_{i=1}^{\tau} r_{p,i+K-\tau+i} \left( \alpha^{(\tau+1-i)}_{t+K+i-(\tau+1)} \right) \right\} \right] = \frac{1}{1 - \gamma} \exp \left\{ (1 - \gamma) \left( B_0^{(\tau)} + B_1^{(\tau)} \mathbf{z}_{t+K-\tau} + \mathbf{z}_{t+K-\tau} B_2^{(\tau)} \right) \right\}.
\]

The Appendix provides a detailed derivation of all these results, as well as expressions for the coefficients of the optimal portfolio policy and the value function.\(^{13}\)

### 4 Optimal growth and value investing

The empirical analysis of optimal dynamic portfolio choice with time-varying investment opportunities has focused primarily on the choice between a well-diversified portfolio of equities representing the market, cash, and - in some cases - long-term bonds. Although this setup allows for the analysis of horizon effects in the allocation to equities relative to cash or bonds, it is not designed to yield insights into horizon effects in the composition of the optimal equity portfolio. Investors might also want to optimally change the composition of their equity portfolio across investment horizons if the covariation of equity returns with state variables is not homogeneous across all types of equities.

Recent work by Campbell and Vuolteenaho (2004) and others has reported empirical evidence of such differences in the risk characteristics of value stocks and growth stocks. Campbell and Vuolteenaho (2004) decompose the covariance of a stock’s unexpected return with the unexpected return on the stock market into the covariance of the return with shocks to aggregate stock cash flows (“stock market cash flow news”) and the covariance of the return with shocks to aggregate stock discount rates (“stock market discount rate news”). They find that the conditional correlation of returns with variables that proxy for time variation in aggregate stock market discount rates is larger for growth stocks than for value stocks, while the conditional

\(^{13}\)In brief, we show in the Appendix that the policy and value function coefficients satisfy a linear recursive relation where the \( A^{(\tau)} \) coefficients depend linearly on the \( B^{(\tau-1)} \) value function coefficients, and the \( B^{(\tau)} \) coefficients depend linearly on both the \( B^{(\tau-1)} \) and the \( A^{(\tau-1)} \) coefficients. The parameters of this linear recursion are nonlinear functions of the parameters of the VAR(1) system, and the coefficient of relative risk aversion. These expressions are algebraically involved but trivial to program, allowing for the examination of portfolio choice problems involving an arbitrary number of assets and state variables. MATLAB routines which execute the policy and value function recursions are available on the authors’ websites.
correlation of returns with changes in aggregate stock market cash flows is larger for value stocks than for growth stocks. They argue that their empirical finding implies that value stocks are riskier than growth stocks from the perspective of a risk-averse, long-horizon investor who holds the market portfolio, because aggregate cash flow shocks appear to be permanent, while aggregate discount rate shocks appear to be transitory.

The flexible framework for the analysis of dynamic portfolio choice problems developed in Sections 2 and 3 is ideally suited for the systematic investigation of value and growth tilts in equity portfolios. To this end, we consider an empirical specification of our dynamic portfolio choice problem in which investors can invest in two equity portfolios, a portfolio of value stocks and a portfolio of growth stocks. We consider two types of investors. The first type of investor can only invest in these two equity portfolios. This is the type of investor implicit in most representative investor models of equilibrium asset prices, which assume that bonds are in zero net supply. The second type of investor is an investor who can also invest in cash (or Treasury bills) and bonds in addition to value and growth stocks. In both cases we explore optimal value and growth tilts across investment horizons and across varying levels of risk aversion. We have also explored a third case where the investor can only invest in cash in addition to value and growth stocks. The results from this case are nearly identical to the case with cash and bonds regarding the allocation to equities and are omitted to conserve space.

4.1 Investment opportunities

4.1.1 Assets, state variables, and data

Following our theoretical framework, we model the dynamics of investment opportunities as a first-order VAR system. As we have already noted, we consider two sets of investable assets and estimate a companion VAR system for each of these investment sets. The first set is comprised only of equities, and consequently, we refer to this set as the “equity-only case.” In this scenario the investor chooses between a value-weighted portfolio of growth stocks and a complementary value-weighted portfolio of value stocks. The value of the two portfolios adds up to the aggregate stock market portfolio. The companion VAR system includes the log real return on the growth stock portfolio (labelled G in tables), the log return on the value stock portfolio (V) in excess of the log return on the growth portfolio (V-G), and a set of common state variables which we describe below.\footnote{We consider V-G instead of V and G separately for consistency with the VAR formulation in our portfolio choice model, which assumes that one of the assets in the investment opportunity set acts as a benchmark asset over which we measure excess returns on all other assets. Since this VAR includes only equity portfolios, the benchmark asset must be one of them. We have chosen the growth portfolio as the benchmark asset, but of course this choice is inconsequential to the portfolio choice results.}

We construct the value and growth portfolios using data on six stock portfolios sorted by the ratio of...
book value of equity to market value of equity (BM) and market capitalization, available from Professor Ken French’s website and based on raw data from CRSP and COMPUSTAT. We begin by aggregating the six portfolios across size terciles to obtain three portfolios – the low, medium and high BM portfolios. We then build the value portfolio (V) as a market capitalization weighted combination of the low BM portfolio with half of the medium BM portfolio. The growth index (G) has the complementary composition. Figure 2 plots the share of total stock market value of these portfolios over time. On average the value portfolio represents 30% of total market capitalization, and the growth portfolio represents the remaining 70%. This split is remarkably stable over time. Growth represents more than 80% of total market capitalization only in three episodes, the early 1930’s, the mid-1970’s and the end of the 1990’s. By contrast, the largest market share of the value portfolio occurs in the late 1940’s, late 1960’s and in the mid 1980’s.

The second investment set adds cash and long-term Treasury bonds to the two equity portfolios, leading us to refer to it as the “equities-and-bonds case.” The companion VAR system includes the log excess return on the value portfolio, the log excess return on the growth portfolio, the log excess return on a constant maturity 5-year Treasury bond (B5), the ex-post real rate of return on a 30-day Treasury bill, and the same set of state variables as in the first system. Excess returns are computed using the 30-day Treasury bill as the benchmark asset.

The common set of state variables includes variables known to forecast aggregate stock excess returns, bond excess returns, interest rates, and inflation. The first of these variables is the price-earnings ratio (PE) on the S&P 500, which forecasts aggregate stock returns negatively at long horizons (Campbell and Shiller 1988, 1998, 2005). The rest of the state variables are related to the term structure of interest rates and inflation. We include the short-term nominal interest rate (t30_YIELD), which forecasts aggregate stock returns negatively (Fama and Schwert 1977, Campbell 1987, Glosten et al. 1993); the yield spread (YSPR), which forecasts bond excess returns positively (Fama and Bliss 1987, Fama and French 1989, Campbell and Shiller 1991, Campbell, Chan and Viceira 2003, Campbell and Viceira 2005); and the ex-post real rate of return on a 30-day Treasury bill (t30_REALRET). Note that the ex-post real rate plays a dual role as the real return on an investable asset (Treasury Bills) and as an additional state variable which, together with the nominal short-term interest rate and the yield spread, allow the VAR system to capture the dynamics of inflation and real interest rates.

---

15 Our results are robust to other possible definitions of the V and G portfolios—for example, using only the first and the third BM portfolios to define V and G, or constructing the V and G indices from the 25 book-to-market/size Fama-French portfolios.

16 An alternative variable that captures similar information in expected aggregate stock returns is the dividend-price ratio. This ratio forecasts future stock returns positively (Campbell and Shiller 1988, Fama and French 1989, Hodrick 1992, Goetzmann and Jorion 1993). Brandt (1999), Campbell and Viceira (1999, 2005), Campbell, Chan, and Viceira (2003) and others use this variable in empirically calibrated models of portfolio choice with time-varying expected stock returns.

17 In their study of the cross-sectional pricing of value and growth stocks, Campbell and Vuolteenaho (2004) consider an additional stock market variable. This variable is the small-stock value spread (VS), which is known to forecast aggregate stock returns negatively (Eleswarapu and Reinganum 2004, Brennan, Wang and Xia 2004, Campbell and Vuolteenaho 2004). The inclusion of this variable does not make any difference to our results, so we have excluded it from our analysis in the interest of parsimony.
Our empirical measure of PE is the value of the S&P 500 portfolio divided by the ten-year trailing moving average of aggregate earnings on the S&P 500 companies, which we obtain from CRSP and Professor Robert Shiller’s website. We have also used the empirical measure of PE of Campbell and Vuolteenaho (2004) with similar results. The data source for bond returns, interest rates and inflation is CRSP. The return on bonds is the log return on a constant maturity 5-year Treasury bond from the CRSP US Treasury and Inflation database. The nominal short rate is the log yield on a 30-day Treasury bill from CRSP. The yield spread is the difference between the log yield on a five-year discount bond from the CRSP Fama-Bliss files, and the log yield on the 30-day Treasury bill. Finally, we use the CPI inflation series in the CRSP US Treasury and Inflation database to construct the ex-post real short-term interest rate and the real return on the growth stock portfolio. We provide full details of the variable definitions and construction in Table 1.

Because we do not observe the relations between state variables and asset returns, we estimate both VAR systems using monthly data for the period December 1952 through December 2003. We restrict our sample to the post-1952 period because the Federal Reserve kept short-term nominal rates essentially fixed before the Treasury Accord of 1952, making it impossible to capture interest rate dynamics using the pre-1953 data series. In our subsequent portfolio choice exercise, we also assume that investors take the VAR parameter estimates at face value, ignoring estimation uncertainty.

4.1.2 VAR estimates

Table 2 presents descriptive statistics of the variables included in the VAR system. This table provides a clear illustration of the empirical regularity known as the “value premium.” While the value stock portfolio, the growth stock portfolio and the aggregate stock market portfolio have almost identical short-term return volatility, the average return on the value stock portfolio is significantly higher than the average return on the growth stock portfolio and the aggregate stock portfolio. The average spread between the returns on value stocks and the returns on growth stocks is about 2.45% per year.\textsuperscript{18} This spread however exhibits non-trivial variation over time and has an annualized standard deviation of nearly 7%. Overall, the Sharpe ratio on the value portfolio is 0.61, which is about 47% larger than the Sharpe ratio on the growth portfolio. Thus from a purely myopic perspective, the ex-post performance of the value portfolio suggests that it represents a more attractive investment opportunity than the growth portfolio.

Table 3 presents estimates for the equity-only VAR system. The table has two panels. Panel A reports the slope coefficient estimates with heteroskedasticity and autocorrelation consistent t-statistics below in parenthesis, and bootstrapped 95% confidence intervals in brackets. The bootstrap estimates are generated

\textsuperscript{18}This estimate of the value premium is cautious because it is computed using the return series on two highly-aggregated portfolios (see Section 4.1.1). If we exclude the middle BM portfolio in the construction of the value (V) and growth (G) indices, the value spread rises to 4.01% per year. The spread increases even further when the extreme quintile BM portfolios are taken to represent V and G.
from sample paths simulated under the null hypothesis that the estimated VAR model represents the true data generating process. The rightmost column in the panel reports the \( R^2 \) for each equation, and the p-value of the F-statistic of the overall significance of the slopes in each equation. Panel B reports the percentage standard deviation of the innovations to each equation (on the main diagonal) and the cross-correlations of the innovations (off the main diagonal).

Panel A in Table 3 shows that own lagged returns forecast returns positively, though only the coefficient on the lagged return on V-G is statistically significant. PE, the nominal short rate, and the ex-post real short rate are all highly significant in the forecasting equation for the real return on the growth stock portfolio. Both PE and the nominal short interest rate forecast the real return on growth stocks negatively, and the ex-post real rate forecasts this return positively. By contrast, none of the state variables is significant in the forecasting equation for the return on V-G. This implies that these variables forecast the return on the value stock portfolio with coefficients which are not statistically different from the coefficients in the equation for the return on the growth stock portfolio. Table 4, which considers the return on the value stock portfolio separately from the return on the growth stock portfolio, confirms this result. In the case of PE, even the point estimate of its coefficient in the V-G equation is essentially zero.

These results show that variables known to forecast aggregate stock market returns also forecast both the returns of growth stocks and the returns on value stocks separately. Of course, that this holds for the growth portfolio is not surprising, since this portfolio represents about 70% of total market capitalization. It is perhaps less obvious that these variables would also forecast the return on the relatively small value stock portfolio.

Panel A in Table 3 also indicates that the state variables are all well described as persistent autoregressive processes. Except for the ex-post real rate, the autoregressive coefficients for all the state variables are above .90 and, in some cases, above .99. This raises the question of whether the processes for the state variables are unit-root processes rather than highly persistent, but ultimately stationary, processes. Recent research (Campbell and Yogo, 2005) supports the second conclusion, which we adopt in our portfolio choice exercise. Finally, it is interesting to note that there exist some cross-forecasting effects in the equations for the state variables. The ex-post real short rate and the yield spread forecast PE positively, while the nominal short rate forecasts the ex-post real short rate positively, and PE negatively.

As the results in Sections 2-4 show, the optimal portfolio allocations depend not only on the slope coefficients in the VAR, but also on the variance-covariance structure of the innovations to the VAR variables. Panel B in Table 3 presents this matrix for the equity-only VAR system. Two facts stand out from this panel.

---

19 We have estimated a VAR system for the real return on the market portfolio with the same state variables. Our estimate confirms that these three state variables forecast aggregate stock market returns in the same direction and with similar statistical significance in our sample period.
First, the correlation between the unexpected return on growth stocks and the unexpected return on V-G is about $-40\%$. The negative of this correlation determines the sign of the one-period GMV portfolio allocation to value stocks in the equity-only case—see equation (17). Its negative sign implies that this portfolio loads positively on value stocks.

Second, shocks to PE are highly positively correlated with unexpected returns on the growth stock portfolio, and negatively correlated with unexpected returns in V-G. This implies that innovations to PE are more correlated with unexpected returns on the growth portfolio than with unexpected returns on the value portfolio. Since innovations to PE proxy for innovations to expected returns on the aggregate stock market portfolio, our results suggest—consistent with the evidence in Campbell and Vuolteenaho (2004)—that returns on growth stocks covary more with stock market discount rate news than the returns on value stocks. We validate this conclusion by bootstrapping the distribution of the covariance estimator under the null hypothesis of an equal covariance between innovations to value and growth and PE. Our simulation reveals that the historical estimate of the covariance between shocks to the value-growth spread and PE is sufficient to reject the null hypothesis at the 0.01%-level (the maximal theoretical level possible under a simulation with 10,000 paths).

Table 4 presents estimates for the equities-and-bonds VAR system. We present constrained estimates in which only the lagged values of the state variables forecast future returns. We have chosen to constrain this system because lagged returns, particularly lagged bond returns, forecast next period’s returns at monthly frequencies positively. This short-lived “momentum” effect induces short-horizon effects in portfolio allocations unrelated to the effects of persistent changes in investment opportunities, which are well captured by our state variables. Because our primary interest is in long-horizon effects in portfolio allocations, we choose to present constrained estimates for the equities-and-bonds VAR system, and portfolio allocations based on these constrained estimates.\(^{20}\)

The estimation results for the equities-and-bonds VAR system are consistent with the estimates of the equity-only VAR system. Panel A shows that PE forecasts the excess returns on both the value and growth portfolios negatively, with similar coefficients in both equations. The nominal short rate also forecasts the excess return on both portfolios negatively. Table 4 also considers the real return on Treasury bills (or ex-post real short interest rate) and the excess return on long-term bonds. It shows the well known result that the yield spread forecasts bond excess returns positively, with a t-statistic above 4. It also shows that the nominal short rate weakly forecasts bond excess returns with a positive sign. The yield spread and the nominal short rate all forecast the real return on T-bills. In both tables, the $R^2$'s of the return forecasting equations are below 5%. This magnitude is typical of return forecasting equations at monthly frequencies, and it implies considerably larger $R^2$'s at lower frequencies (Campbell and Thompson, 2005).

Panel B in Table 4 shows the covariance structure of innovations in the equities-and-bonds system.

\(^{20}\)Unconstrained VAR estimates and the associated portfolio allocations are available from the authors upon request.
The upper left block of the table shows the covariance structure of unexpected excess returns. Unexpected excess returns on value stocks are highly positively correlated with unexpected excess returns on growth stocks. Both portfolios show similar low positive correlations with the real return on T-bills and bonds. The upper right block shows the correlation structure of unexpected returns with the state variables. We have already discussed the large positive correlation of unexpected returns on growth stocks with PE. Unexpected returns on value stocks are also positively correlated with shocks to PE, but their correlation is smaller than the correlation of growth stocks with shocks to PE. This is consistent with the negative correlation between shocks to PE and the unexpected return on V-G shown in Table 3. We have already noted that this lower correlation implies that value stocks are less correlated with innovations in aggregate stock market discount rates than growth stocks. As we show below, this has important implications for our asset allocation results. Finally, unexpected excess returns on bonds are highly negatively correlated with the short nominal interest rate (Campbell, Chan and Viceira 2003, Campbell and Viceira 2005).

4.2 Portfolio allocations in the equity-only case

We now examine the optimal portfolio allocation of a $K$-period, power-utility investor who is constrained to invest only in two portfolios of equities—a value stock portfolio and a growth stock portfolio—and behaves as if investment opportunities evolved according to the equity-only VAR of Table 3. Section 4 shows that the optimal portfolio rule for this investor is an affine function of the vector of state variables, with coefficients that change with the investor’s investment horizon. To facilitate interpretation, we omit reporting these coefficients and instead present our results in the form of plots with mean percentage portfolio allocations to each asset across different investment horizons. Given the affine form of the portfolio rule, the mean portfolio allocation at any horizon is simply the optimal portfolio rule evaluated at the unconditional mean of the vector of state variables. We consider horizons between 1 month, at the left end of the plots, and 300 months (or 25 years) at the other end.

The 1-month mean percentage allocations correspond to the one-period myopic allocation described in equation (14). We have shown that the myopic portfolio allocation is a weighted average of the one-period mean-variance efficient tangency portfolio (16) and the one-period mean-variance efficient GMV portfolio (17), with weights $1/\gamma$ and $(1 - 1/\gamma)$. Thus a short-term log utility investor holds only the tangency portfolio, and a short-term, infinitely risk averse investor holds only the GMV portfolio.

Table 5 shows the composition of the tangency portfolio and the GMV portfolio in the equity-only case and in the equities-and-bonds case. The tangency portfolio is heavily tilted toward value stocks. A short-term log utility investor holding this portfolio invests on average about 572% of her wealth in the value portfolio, and finances this long position with a 472% short position in growth stocks. Table 2 and Table 4 help in understanding the value tilt in the tangency portfolio. Table 2 shows that the mean return on the value portfolio is larger than the mean return on the growth portfolio, and Table 4 shows that the
returns on the value portfolio are highly positively correlated with the returns on the growth portfolio. This large positive correlation (90%) implies that, from the perspective of a short-term investor, value and growth stocks are close substitutes. Thus a modestly risk averse myopic investor will try to take advantage of the mean return spread between value and growth by taking aggressive long and short positions in value and growth stocks, respectively.

The GMV portfolio is also heavily tilted toward value stocks—about 90% long value stocks. With a short-run return correlation of 90% between the return on the value stock portfolio and the growth stock portfolio, the GMV portfolio is heavily tilted toward the portfolio with the smallest return volatility, which Table 4 shows is the value stock portfolio.\footnote{Another way to understand this result is to apply equation (17), which describes the GMV portfolio, to the only-equities case. Equation (17) implies that the GMV portfolio allocation to value stocks is equal to the negative of the correlation between the unexpected return on growth stocks with the unexpected return on V-G, times the ratio of return volatilities. Table 3 shows that this correlation is about $-41\%$, and the ratio of volatilities is about 2.3. The product of these two quantities is .93, which is the GMV allocation to value stocks.}

Figure 3 presents plots of the mean percentage allocation to growth and value for an investor with coefficients of relative risk aversion of 2 (Panel A), 5, 10 and 20 (Panel B), and 500 (Panel C). These figures show that the composition of the optimal portfolio changes dramatically across investment horizons. The left end of the plots shows the 1-month myopic portfolio allocations which, consistent with the results shown in Table 5, is largely invested in the value stock portfolio with short positions in the growth stock portfolio. But as we consider longer investment horizons, the mean optimal allocation to value decreases—and correspondingly the mean allocation to growth increases—and eventually flattens out.\footnote{The pattern is monotonically decreasing for most coefficients of relative risk aversion. However, for some investors there is a slight increase in the value allocation as they move from a 1-month horizon to a 2-month horizon. As we have already noted, this short-term effect is caused by lagged return predictability.} Interestingly, the reduction in the value tilt of the portfolio becomes more pronounced as we consider increasingly risk averse investors. This reflects an intertemporal hedging demand for growth stocks which is increasing in risk aversion and investment horizon.

Panel C in Figure 3 makes this point clear. This panel plots the mean portfolio allocation of an investor who is effectively infinitely risk averse.\footnote{We show in the Appendix that the optimal portfolio policy converges to an envelope as $\gamma \to \infty$. In this particular application, the convergence occurs for values of $\gamma$ in the vicinity of 500.} This investor chooses the least risky portfolio at any given investment horizon, regardless of expected return. Of course, at short horizons this is the GMV portfolio, which Table 5 and the leftmost point in the plots show is 90% invested in the value portfolio, and only 10% invested in the growth portfolio. But intertemporal hedging considerations lead highly conservative investors with longer investment horizons to move away from value into growth. For investors with horizons of about 4 years (or 48 months), the least risky portfolio is already 50% in value stocks and 50% in growth stocks. At horizons of about 12 years (or 144 months), the long-run least risky portfolio is about 30% in the value portfolio, and 70% in the growth portfolio. Interestingly, this portfolio is very close to the aggregate stock market portfolio, suggesting that the least risky portfolio of a long-term, all-equity
investor has no value tilt or a very small tilt.

In order to best understand the increasing allocation to growth as a function of the agent’s risk aversion and investment horizon it is useful to consider the two components of total portfolio demand. Since equation (14) implies that the mean myopic portfolio demand is constant across all investment horizons, the entire variation across investment horizons in total portfolio demand we observe in Figure 3 must be ascribed to the hedging component of portfolio demand. Thus the increasing allocation to growth as investment horizon and risk aversion increase reflects intertemporal hedging considerations. Growth stocks appear to be less risky than value stocks to long-term investors because they help investors hedge temporary fluctuations in aggregate stock market discount rates.

4.3 Portfolio allocations in the presence of bonds and cash

We now examine the optimal portfolio strategies of investors who can invest in long-term nominal bonds and Treasury bills, in addition to the value and the growth stock portfolios. As mentioned, an additional case which allows only for cash in addition to value and growth stock portfolios produces nearly identical results regarding the allocation to equities, and it is omitted to save space. This section assumes that investors view investment opportunities as reflected in the VAR estimates of Table 4. Figures 4 and 5 show the mean portfolio allocations to each asset of investors with different coefficients of relative risk aversion and investment horizons. (The layout of these figures is identical to the asset allocation figures described in Section 5.2.) Investors with moderate levels of risk aversion (Figure 4) take long levered positions in the value stock portfolio and the long-term bond, financed with short positions in the growth stock portfolio and cash. As expected, the degree of leverage decreases as we consider increasingly risk averse investors.

In contrast with Panel B in Figure 3, Panel A in Figure 4 indicates that when cash and long-term bonds are made available to moderately risk averse equity-only investors, the optimal allocation to value increases with the horizon, albeit slowly. Moreover, rather than finance the expansion in the allocation to value through a commensurate reduction in the allocation to growth, the allocation to growth increases as well. In fact, the magnitude of the increase in the allocation to growth stocks appears to be somewhat larger than the increase in the allocation to value stocks. For example, the investor with a coefficient of relative risk aversion of 5 increases her allocation to growth from about $-0.87$ at a one-month horizon to about $-0.64$ at a 25-year horizon—an increase of 23 percentage points—, and increases her allocation to value from about 1.46 at a one-month horizon to about 1.63 at a 25-year horizon—a increase of only 17 percentage points.

The relatively larger magnitude of the increase in the allocation to growth stocks relative to value stocks becomes even more transparent when we rescale the allocation to each portfolio by the total equity allocation $(\bar{\alpha}_V + \bar{\alpha}_G)$ at the corresponding horizon, as in Lynch (2001). Panel B in Figure 4 plots the
rescaled allocations to growth stocks and value stocks, and shows that indeed the allocation to growth stocks relative to the total allocation to equities increases with investment horizon, while the allocation to value stocks decreases. Our findings generally corroborate and extend the results reported in Lynch (2001) for an investor with a coefficient of relative risk aversion of four who has cash, value stocks and growth stocks available for investment.

However, it is not clear whether the increase in the allocation to growth stocks at long horizons is of the same nature as the increase we have reported for equity-only investors, because the allocation to value also increases with investment horizon. The increased allocation to growth relative to value at longer investment horizons could be the result of the investor’s desire to optimally increase the overall allocation to the value-weighted stock market portfolio, with no particular desire to actively tilt the portfolio toward growth relative to value.

To examine this hypothesis, we compute value and growth tilts in the optimal portfolio at each investment horizon as the deviation in the optimal portfolio weights relative to the composition of the market portfolio. Consistent with the evidence shown in Figure 1, we take the composition of the stock market portfolio to be 30% value and 70% growth. This methodology allows us to separately examine the variation in the total equity allocation across horizons and compositional shifts in the equity portfolio. It also underscores the equilibrium significance of the market portfolio, and coincides with the practitioner definition of an active position when the market portfolio is taken as the benchmark for the overall equity allocation.

Specifically, we transform the optimal allocations to growth and value into an equivalent allocation to the market portfolio and a value tilt. To do this we compute the mean total stock market exposure of a portfolio at any horizon as \( \bar{\gamma}_G / 0.7 \), where \( \bar{\gamma}_G \) is the mean portfolio allocation to the growth stock portfolio. The mean active value tilt of the portfolio is then given by \( \bar{\gamma}_V - (0.3 / 0.7) \bar{\gamma}_G \), where \( \bar{\gamma}_V \) is the mean portfolio allocation to the value stock portfolio.24 Figure 5 plots the allocation to the overall equity market and the active value tilt (with respect to the market portfolio) implicit in the equity allocations presented in Figure 4. The active tilt is toward value when the allocation shown in the plot is positive, and toward growth when it is negative. Figure 5 reveals that the portfolios of short-horizon investors have a value tilt, which is very pronounced for aggressive investors, combined with a short position in the market portfolio. Interestingly, the value tilt remains fairly constant as we consider longer investment horizons. By contrast, the short position in the market portfolio becomes smaller as the investment horizon increases.

Thus these results suggests that after accounting for the propensity of the investor to increase her total equity allocation as the horizon increases, the mean value tilt of the optimal allocation appears to be positive and stable across investment horizons. Long-horizon stock investors hedge time variation in

24 The results obtained using this methodology are essentially equivalent to those that arise from re-estimating the VAR model in Table 3, but replacing the growth portfolio with the market portfolio.
investment opportunities by increasing their exposure to the overall stock market portfolio, but they do not revise their tilt towards value stocks as the investment horizon varies. Thus the increasing allocations to growth and value observed in Figure 4 simply reflect that investors with low or moderate levels of risk aversion increase their allocation to equities at long horizons.25

Finally, Figure 6 plots the mean portfolio allocation to Treasury bills, long-term bonds, the market portfolio, and the active value-growth tilt for an investor who is effectively infinitely risk averse. This figure shows that growth stocks play no role in the optimal portfolios of highly risk averse investors when bonds and cash are available for investment, regardless of horizon. Brennan and Xia (2000), Campbell and Viceira (2001), Wachter (2003) and others have shown that highly risk averse investors are interested in hedging time variation in real interest rates, rather than time variation in expected stock returns. For these investors the optimal portfolio strategy is to be fully invested in a zero-coupon, inflation-indexed bond that matches their investment horizon. When this bond is not directly available to them, investors will try to synthesize it out of the menu of available assets. Figure 6 shows that the portfolio that best synthesizes this bond out of cash, a constant maturity nominal long-term bond, and value and growth equities, is a mix of cash and the nominal long-term bond. The weight of cash in this mix decreases as horizon increases. Growth stocks do not play any role in the portfolio of these investors, suggesting that they are not particularly good hedges of bond returns.

4.4 The value of dynamic rebalancing

Our empirical analysis so far has focused on the portfolio allocations to value and growth stocks implied by the optimal dynamic portfolio strategy (22) of Section 4. Under this strategy, investors dynamically vary their portfolio shares each period in response to changes in investment opportunities. They also change portfolio shares as their investment horizon shortens, even if investment opportunities do not change from one period to the next—this is the effect captured by the $A_i^{(r)}$ coefficients and reflected in the mean allocation plots in Section 5.

In practice, however, investors might not revise their investment policy continuously. For example, many institutional and individual investors adopt long-horizon asset allocation policies that are revised at lower frequencies, typically annually. In the interim, the portfolio weights are either held constant or allowed to drift. This section explores the effect of decreasing the frequency with which investors revise their asset allocation policy on the welfare of investors with different investment horizons and risk aversion coefficients. In our computations we adopt the convention that portfolio weights are held constant between policy re-evaluation dates, but our results are largely unaffected if the weights are allowed to drift.

---

25 Campbell and Viceira (1999, 2002, 2003) and others have shown that investors use the aggregate stock market portfolio to hedge time variation in expected stock returns. Since realized stock returns tend to increase at times when expected stock returns decrease, investors whose coefficient of risk aversion exceeds one will have a positive positive intertemporal hedging demand for equities.
To examine the welfare loss in detail, we take advantage of the fact that the VAR(1) class of models is closed under temporal aggregation—see proof in the Appendix. This allows us to aggregate the systems we estimate using monthly data to any desired frequency, and to examine the value of the rebalancing frequency to the investor. We evaluate the welfare effects using the value function (23), which is based on our approximation (11) to the instantaneous return on wealth. Although Campbell, Chacko, Rodriguez and Viceira (2004) show that the approximation to the log return on wealth is highly accurate even when applied to low-frequency returns, additional care is necessary to understand how these one-period errors cumulate over the long-horizons considered in the paper. To ensure that our results are robust to the use of the approximation, we have repeated our numerical simulations using exact portfolio returns. We find that our results are qualitatively unchanged and quantitatively only slightly affected, so we choose to present the results based on the approximation to maintain consistency with the analytical derivations of the paper.26

Table 6 explores the welfare effect of decreasing the rebalancing frequency in the context of the equity-only case. Our base case is the dynamic strategy (22) with a monthly rebalancing periodicity, which we extend gradually to a quarter, half-year, and one year. Panel A shows the certainty equivalent of the dynamically rebalanced strategy (21) in the equity-only case. Panel B reports the welfare losses of dynamic strategies with lower rebalancing frequencies. All welfare losses are computed as the percentage difference between the certainty equivalent of the strategy with limited rebalancing and the certainty equivalent of the strategy with monthly rebalancing.27 Panel C reports the largest monthly management fee which an investor constrained to follow a strategy with limited rebalancing would pay to gain access to the monthly dynamically rebalanced strategy. These fees re-scale the welfare losses in Panel B to facilitate comparisons across investment horizons.28

Panel B shows that the welfare loss from not rebalancing dynamically at a monthly frequency increases as we lower the rebalancing frequency. Controlling for rebalancing frequency, total welfare loss rises as the investment horizon increases (more time to exploit return predictability) and as risk-aversion decreases (more aggressive portfolio positions). At long horizons, welfare losses are large for all investors, but they

26 Results based on exact portfolio returns are readily available upon request.
27 In both strategies we hold weights constant between rebalancing dates, and we use simulated data at a monthly frequency. To compute the certainty equivalent measure for each rebalancing frequency we simulate 20,000 paths of the VAR system shown in Table 2. Next we compute the optimal strategy (22) along each path. This allows us to compute the realized terminal wealth and realized utility of terminal wealth for each path. We then average realized utility across paths to obtain our measure of expected utility. This measure is subsequently inverted to obtain a certainty equivalent of wealth. We use the same set of simulated paths to evaluate combinations of the investment horizon, risk aversion and rebalancing frequency, and for each rebalancing frequency we appropriately perform a temporal aggregation of the VAR system.
28 Specifically, the fee φ is computed as the solution to

\[(1 + g)(1 - φ) = (1 + g_{\text{const}}),\]

where g and g_{\text{const}} are the monthly growth rates implied by the certainty equivalent of wealth of the monthly dynamic rebalancing strategy and the constrained rebalancing strategy respectively. If W_{CE} denotes the certainty equivalent of wealth, the growth rate is equal to \((W_{CE})^{1/K} - 1.\)
are particularly large for aggressive investors. For example, at a horizon of 25 years (or 300 months) and at an annual re-evaluation frequency, the welfare loss is 56.0% for log utility investors and about a fourth of that (a large 11.9%) for investors with coefficient of relative risk aversion of 10.

The normalization of welfare losses shown in Panel C suggests however that welfare losses are roughly similar across investment horizons for all investors with the same re-evaluation frequency. Of course, they increase as we consider longer re-evaluation intervals.

In general, Table 6 shows that long-horizon, log utility investors are the investors who suffer the largest welfare losses from not re-evaluating their policy portfolios frequently. These investors change their portfolios in response to changes in expected returns, but choose their portfolios disregarding any intertemporal hedging considerations. Thus for these investors welfare losses are all about the timing value of predictability. By contrast, intertemporal hedging considerations in optimal portfolio decisions become more important as we consider increasingly risk averse investors. The relatively small welfare losses for conservative investors from not re-evaluating their portfolios frequently suggest that intertemporal hedging portfolio demands are relatively stable over time, and change only slowly in response to changes in expected returns. Table 7 illustrates this intuition.

Table 7 reports the monthly standard deviation of the portfolio allocation to value—the volatility of the portfolio allocation to growth is identical—and the ratio of the standard deviation of the intertemporal hedging demand to value over the standard deviation of the total portfolio demand for investors with coefficients of relative risk aversion of 5, 10, and 500, and investment horizons of 12 months, 60 months, 120 months, and 300 months. This table shows that the volatility of total portfolio demand does not change across investment horizons, but it declines dramatically as we consider increasingly risk averse investors. For example, the monthly volatility of the allocation of an investor with a coefficient of relative risk aversion of 2 is about 400% per month, while the corresponding volatility for an investor with a coefficient of relative risk aversion of 500 is less than 2%. Most interestingly, this table shows that most of portfolio volatility is caused by the variability of the myopic component. The fraction of total portfolio volatility due to intertemporal hedging is very low for all investors regardless of their risk aversion: It is always smaller than 5%. Thus while intertemporal hedging accounts for all the variability of portfolio demand across investment horizons, myopic portfolio demand accounts for almost all of the variability of portfolio demand over time. This helps understand why welfare losses from following a low frequency re-evaluation policy are much smaller for highly conservative all-equity investors than for aggressive all-equity investors.

Next we turn to the welfare analysis of the case when the investable universe is expanded to include T-bills and the 5-year bond. This is shown in Table 8, whose structure is identical to Table 6. Although we find an identical set of patterns of welfare losses across re-evaluation frequencies, investment horizons and

29. To see this note that the myopic portfolio demands add up to one, and the intertemporal hedging demands add up to zero. Thus the total portfolio allocation to growth is just one minus the total portfolio allocation to value.
levels of risk aversion, their magnitudes are much larger than in the all-equities case, particularly for highly risk averse investors. For example, the welfare loss from following a strategy with an annual re-evaluation frequency ranges from 98.9% (when $\gamma = 1$) to 55.1% (when $\gamma = 10$) for investors with a 25-year investment horizon. These differences in the certainty equivalents of wealth imply maximal management monthly fees of 1.49% and 0.27% per month, or 17.9% and 3.2% per year, respectively.

This result suggests that with an expanded investment set, infrequent re-evaluation of investment policies is very costly to all investors when cash and bonds are also included in the menu of available assets. It is very costly to aggressive investors because it is optimal for them to adopt highly variable myopic portfolio demands. It is also very costly to highly conservative investors because their intertemporal hedging demands also change as their horizon shortens and they try to change the relative allocation to cash and bonds to synthesize the inflation-indexed bonds that best matches their investment horizon.

5 Conclusion

This paper makes several contributions to the theory and practical implementation of modern portfolio theory. First, it examines the portfolio choice problem of a long-term investor with isoelastic utility of wealth at a finite horizon, who faces time variation in expected returns and interest rates described by a first-order vector autoregressive system. The paper develops closed form solutions for the problem, and provides useful economic insights on horizon effects on portfolio choice based on the distinction between geometric mean returns and arithmetic mean returns. We show that the optimal dynamic rebalancing strategy is affine in the vector of state variables describing investment opportunities, with coefficients that change with investment horizon. This solution is based on an approximation to the log return on wealth which becomes increasingly accurate as the frequency of rebalancing increases, and it is exact in continuous time. As such, our solution is a discretized version of the continuous time solution obtained by Liu (2007). An important advantage of this solution is that it can be readily implemented for investment opportunity sets with any number of assets and state variables. By contrast, existing analytical models do not allow for simultaneous time variation in risk premia and interest rates—with the exception of the approximate solution in Campbell, Chan and Viceira, (2003)—, and traditional numerical solution methods, which can handle both, become difficult to apply in problems with more than a few state variables. Thus our solution method provides a step forward toward the practical implementation of dynamic portfolio choice models with realistically complex investment opportunity sets.

Second, we apply our method to study the practically relevant problem of value and growth investing at long horizons. We consider two types of investors: Investors who can only invest in equities, which is the type of investor implicit in representative agent equilibrium models, and investors who can also invest in short-term and long-term bonds in addition to equities.
We find that on average equity-only investors with short horizons optimally choose portfolios heavily tilted toward value and away from growth, regardless of their risk aversion. Aggressive short-term investors find it optimal to hold long large positions in value stocks offset by large short positions in growth stocks, because the mean return spread between value and growth is positive, and their returns are highly positively correlated. Highly risk averse short-term investors hold large positions in value stocks because of their smaller return volatility and high correlation with growth. However, the optimal allocation to value decreases dramatically—and correspondingly the optimal allocation to growth increases—for investors with longer horizons. This effect is strongest for long-horizon, highly risk averse investors, who hold large long positions in growth stocks. The increasing portfolio demand for growth stocks across investment horizons is driven by intertemporal hedging motives. Growth stocks are better suited than value stocks to hedge against adverse changes in investment opportunities in the equity market, because they are more highly negatively correlated with changes in aggregate stock discount rates than value stocks are. Thus long-horizon “representative” investors find value stocks riskier than growth stocks, and see the unconditional value spread as a risk premium for bearing this risk.

We also consider investors who can choose among value stocks, growth stocks, cash, and long-term bonds. In this case, we find that investors willing to hold equities in their portfolios still increase their allocation to growth stocks as their investment horizon lengthens. This demand is once again driven by intertemporal hedging motives. However, in this case they have the ability to increase their portfolio demand for growth stocks without sacrificing their exposure to value stocks. We find that the active value tilt—relative to the aggregate market exposure—of these investors remains fairly stable across investment horizons. These investors increase their allocation to growth stocks as investor horizon lengthens as part of their desire to optimally increase their aggregate stock exposure. As we consider increasingly risk averse investors, they shift out of equities and into fixed income instruments. Short-horizon, highly risk averse investors hold large positions in cash, while long-horizon highly risk averse investors hold large positions in long-term bonds.

Third, we compare the welfare loss to investors from using constrained portfolio rules instead of the unconstrained dynamic rebalancing strategy. We consider the welfare loss from infrequent re-evaluation of portfolio policies relative to the optimal dynamic strategy as we vary the horizon and re-evaluation frequencies. For all-equity investors, we find that the welfare losses from infrequent rebalancing are significant for long-horizon investors with low risk aversion coefficients. By contrast, moderately risk averse, long horizon all-equity investors do not face large welfare losses from adopting asset allocation policies that are reevaluated infrequently. For long-horizon investors who can invest in equities, bonds, and cash, welfare losses from adopting investment policies with infrequent re-evaluation of portfolio weights are large, regardless of their risk aversion coefficient.

This paper develops a flexible analytical framework for the study of dynamic portfolio choice problems with a large number of assets and state variables. This flexibility is enhanced by modeling investment
opportunities as a VAR(1), which is extremely easy to estimate from data. However, the model has important limitations that should be kept in mind. First, the model ignores intermediate consumption or labor income, which are relevant for individual investors. Campbell, Chan, and Viceira (2003) also study a high-dimensional portfolio choice problem with intermediate consumption, but their solution is accurate only when the optimal consumption-wealth ratio is not too variable. Second, our model does not consider short-sales or borrowing constraints. Allowing for either of these constraints would take us outside the realm of analytically tractable models, and would require a fully numerical solution which might be difficult to implement in high-dimensional problems. Constraints typically ameliorate the extreme positions that unconstrained models sometimes recommend based on the capital market assumptions of the investor, but they do not often change the direction of those recommendations. Thus an unconstrained solution is an essential step in any asset allocation problem, since it allows for an examination of the economic implications of the investor’s view of investment opportunities. Third, when the VAR parameters are estimated from data, we assume that investors take them at face value, ignoring estimation uncertainty or learning (Brennan 1998, Xia 2001). Of course, one could consider investors who weight the empirical likelihood function with priors that are not fully informative. Previous research suggests that, as long as investor’s priors are not completely diffuse, allowing for parameter uncertainty typically results in portfolio allocations which are a smoothed version of the allocations that result from ignoring it (Kandel and Stambaugh 1996, Barberis 2000, Wachter and Warusawitharana 2005). Investigation of highly dimensional models with labor earnings uncertainty, portfolio constraints, and parameter uncertainty and learning are important directions for future research.

A Appendix: Model setup

In this section we introduce the VAR(1) specification describing the evolution of the risky asset returns and the state variables used to forecast them. We then present the Campbell-Viceira (2003) approximation to the log portfolio return, state the formulas relating the single-period VAR moments to their long-horizon counterparts, and introduce the selector matrix notation used in the ensuing derivations.

A.1 VAR(1) Model

The vector being modeled as a first order auto-regression, $z_{t+1}$, is comprised of the log return on the benchmark asset ($r_{1,t+1}$), the excess log returns on the $n$ risky assets computed in relation to the benchmark asset ($x_{t+1}$) and the $m$ state variables ($s_{t+1}$), which characterize the investment opportunity set and are assumed to have predictive power for the asset returns. The dynamics of the vector auto-regression are given by:

$$z_{t+1} = \Phi_0 + \Phi_1 z_t + v_{t+1}$$

where $z_{t+1}$ is:

$$z_{t+1} = \begin{bmatrix} r_{1,t+1} \\ x_{t+1} \\ s_{t+1} \end{bmatrix}$$

The VAR(1) model is parameterized by: an $(1+n+m) \times 1$ vector of intercepts - $\Phi_0$, and an $(1+n+m) \times (1+n+m)$ matrix of slope coefficients - $\Phi_1$. The $(1+n+m) \times 1$ vector of shocks $v_{t+1}$ has a mean zero multivariate normal distribution with covariance matrix:

$$\Sigma_v = \begin{bmatrix} \sigma_x^2 & \sigma_x \Sigma_x & \sigma_x \Sigma_{xs} \\ \sigma_x \Sigma_x & \Sigma_{xx} & \Sigma_{xss} \\ \sigma_x \Sigma_{xs} & \Sigma_{xss} & \Sigma_{ss} \end{bmatrix}$$

A.2 Portfolio return approximation

Following Campbell and Viceira (QJE 1999), we approximate the log return on the portfolio as:

$$r_{p,t+1} = \alpha' x_{t+1} + r_{1,t+1} + \frac{1}{2} \alpha' \left( \sigma_x^2 - \Sigma_{xx} \alpha \right)$$

where $\sigma_x^2 \equiv \text{diag}(\Sigma_{xx})$, is the vector consisting of the diagonal elements of $\Sigma_{xx}$, the variances of the excess returns. The accuracy of this approximation increases with the rebalancing frequency, and is exact in the limit of continuous trading.

A.3 Conditional K-period moments

In order to assess the value an agent places on the ability to re-balance his portfolio at intermediate dates, when his objective is to maximize the utility of terminal wealth, it is necessary to consider some benchmark portfolio strategies where the opportunity for re-balancing is restricted. The two most intuitive cases are: one period (myopic) portfolio choice based on K-period return moments and a strategy in which the portfolio weights are chosen at inception and held constant across time (i.e. re-balanced each period to fixed proportions). Because we examine portfolio choice decisions over relatively long horizons the latter strategy is more plausible, as agents are unlikely to allow their weights to drift significantly without intervening.
Furthermore, our analytical solutions are based on an approximation to the log portfolio return, which is only accurate at short horizons.

Both of the benchmark strategies require the computation of the conditional K-period moments of the VAR variables, and we present these results here for completeness:30

\[
E_t \left[ \sum_{i=1}^{K} z_{t+i} \right] = \left[ \sum_{i=0}^{K-1} (K - i) \Phi_1^i \right] \Phi_0 + \left[ \Phi_1^K \right] z_t
\]

\[
Var_t \left[ \sum_{i=1}^{K} z_{t+i} \right] = Var_t \left[ \sum_{q=1}^{K} \sum_{p=0}^{K-q} \Phi_1^q \epsilon_{t+q} \right]
\]

In the important case of no predictability (\( \Phi_1 = 0 \)) it is trivial to verify that the moment equations simplify to:

\[
\frac{1}{K} E_t \left[ \sum_{i=1}^{K} z_{t+i} \right] = \Phi_0 \quad \frac{1}{K} Var_t \left[ \sum_{i=1}^{K} z_{t+i} \right] = \Sigma_v
\]

A.4 Selector matrix notation

In order to facilitate matrix operations in the remainder of the derivations we introduce the selector matrix notation. A selector matrix is simply a matrix that, when post-multiplied by the target matrix, returns a set of rows and columns from the target. A selector matrix (operator), \( H \), has equal row and column size as the target matrix and is comprised of zeros and ones. An operator with a single subscript, e.g. \( H_{\phi} \), selects the rows corresponding to the set of variables \( \phi \) from the target matrix; an operator with a double subscript \( H_{\phi\psi} \) first selects the rows corresponding to variable \( \phi \) and then the columns corresponding to variable \( \psi \). In other words if we denote the target matrix \( T \), the double selection operation can be expressed as:

\[
H_{\phi\psi} T = \left( H_{\psi} \left( H_{\phi} T \right) \right)^\prime
\]

Further, we denote the result of selecting the rows and columns corresponding to the set of variables \( ij \) from the target matrix, \( T \), as follows:

\[
H_{ij} T = T_{ij}
\]

If the target matrix already has a subscript (e.g. \( \Phi_0 \) or \( \Phi_1 \)) the selected rows and columns will be indicated with a superscript.

---

30 A detailed derivation can be found in Campbell and Viceira (2005).
B Appendix: The optimal dynamic strategy

The K-period dynamic portfolio choice problem can be solved, without loss of generality, by a recursive extension of the solution for the optimization problem of the last two periods. In order to arrive at the recursive solution we proceed in two steps. First we derive the portfolio rule in the last period (the base case for policy function recursion) and the associated value function (the base case for the value function recursion). Then we solve the problem in the preceding period, as a function of the value and policy function coefficients from the last period. This enables us to isolate the recursive relationship linking the policy function and value function recursions for two adjacent periods.

For the two period case, the investor’s objective remains to maximize:

\[
E_{t+K-2} \left[ \frac{1}{1-\gamma} W_{t+K}^{1-\gamma} \right] = \frac{1}{1-\gamma} W_{t+K-2}^{1-\gamma} E_{t+K-2} \left[ (1 + R_{p,t+K-1})^{1-\gamma} (1 + R_{p,t+K})^{1-\gamma} \right] = \frac{1}{1-\gamma} W_{t+K-2}^{1-\gamma} E_{t+K-2} \left[ \exp \left\{ (1 - \gamma) r_{p,t+K-1} \right\} E_{t+K-1} \left[ \exp \left\{ (1 - \gamma) r_{p,t+K} \right\} \right] \right]
\]

with respect to the sequence of portfolio choices \( \{a_{t+K-2}, a_{t+K-1}\} \). The control variables are indexed by the time at which they are to be applied (subscript) and the time remaining to the horizon (superscript). This convention will allow us to distinguish the fact that while the value of the portfolio weight vector will depend on the realization of the state vector, the characterization of the optimal dynamic policy will only depend on the time remaining to the horizon, \( \tau \).

B.1 Time \( t + K - 1 (\tau = 1) \)

B.1.1 Policy function

The \( (t + K - 1) \) objective function remains unchanged relative to the problem we considered in the previous section:

\[
\max_{a_{t+K-1}} E_{t+K-1} \left[ \exp \left\{ (1 - \gamma) r_{p,t+K} \right\} \right] \equiv \max_{a_{t+K-1}} \exp \left\{ (1 - \gamma) E_{t+K-1} \left[ r_{p,t+K} \right] + \frac{1}{2} (1 - \gamma)^2 Var_{t+K-1} \left[ r_{p,t+K} \right] \right\}
\]

Using the selector matrix notation the first two moments of the portfolio return are now given by:

\[
E_{t+K-1} \left[ r_{p,t+K} \right] = a_{t+K-1}^{(1)} \mathbf{H}_z \left( \Phi_0 + \Phi_1 z_{t+K-1} \right) + \mathbf{H}_z \left( \Phi_0 + \Phi_1 z_{t+K-1} \right) + \frac{1}{2} a_{t+K-1}^{(1)} \left( \sigma^2 - \Sigma_{xx} \alpha_{t+K-1}^{(1)} \right)
\]

\[
Var_{t+K-1} \left[ r_{p,t+K} \right] = a_{t+K-1}^{(1)} \Sigma_{xx} \alpha_{t+K-1}^{(1)} + \sigma^2 + 2 a_{t+K-1}^{(1)} \sigma_{1x}
\]

After substituting the moments into the objective function and simplifying we obtain the following first order condition:

\[
\mathbf{H}_z \left( \Phi_0 + \Phi_1 z_{t+K-1} \right) + \frac{1}{2} \sigma^2 - \Sigma_{xx} a_{t+K-1}^{(1)} + (1 - \gamma) \left( \Sigma_{xx} a_{t+K-1}^{(1)} + \sigma_{1x} \right) = 0
\]

Assuming that the \( \Sigma_{xx} \) is non-singular this equality is solved by:

\[
a_{t+K-1}^{(1)} = \frac{1}{\gamma} \Sigma_{xx}^{-1} \left( \mathbf{H}_z \left( \Phi_0 + \Phi_1 z_{t+K-1} \right) + \frac{1}{2} \sigma^2 + (1 - \gamma) \sigma_{1x} \right)
\]

The optimal portfolio can then be written as an affine function of the \( z_{t+K-1} \) vector and can be expressed as:

\[
a_{t+K-1}^{(1)} = A_0^{(1)} + A_1^{(1)} z_{t+K-1}
\]
where:

\[ A_0^{(1)} = \frac{1}{\gamma} \Sigma_{xx}^{-1} \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 + (1 - \gamma) \sigma_{1x} \right) \]  

(33)

\[ A_1^{(1)} = \frac{1}{\gamma} \Sigma_{xx}^{-1} \Phi_1^x \]  

(34)

**B.1.2 Value function**

We begin the derivation of the last period value function by substituting (32) into the expression for the portfolio return moments in order to express them as a function of the \( A_i^{(1)} \) coefficients:

\[
E_{t+K-1}[r_{p,t+K}] = \left( A_0^{(1)} + A_1^{(1)} z_{t+K-1} \right)' \left( \Phi_0^x + \Phi_1^x z_{t+K-1} \right) + \left( \Phi_0^1 + A_1^{(1)} z_{t+K-1} \right) + \\
\quad + \frac{1}{2} \left( A_0^{(1)} + A_1^{(1)} z_{t+K-1} \right)' \left( \sigma_x^2 - \Sigma_{xx} \left( A_0^{(1)} + A_1^{(1)} z_{t+K-1} \right) \right) \\
= \Phi_1^1 + A_0^{(1)'} \left( \Phi_0^1 + \frac{1}{2} \left( \sigma_x^2 - \Sigma_{xx} A_0^{(1)} \right) \right) + z_{t+K-1} A_1^{(1)'} \left( \Phi_0^1 + \frac{1}{2} \left( \sigma_x^2 - \Sigma_{xx} A_0^{(1)} \right) \right) + \\
\quad + \left( \Phi_1^1 + A_0^{(1)'} \left( \Phi_1^1 - \frac{1}{2} \Sigma_{xx} A_1^{(1)} \right) \right) z_{t+K-1} + z_{t+K-1} A_1^{(1)'} \left( \Sigma_{xx} A_1^{(1)} + 2 \sigma_{1x} \right) \\
\quad + z_{t+K-1} A_1^{(1)'} \left( \Sigma_{xx} A_1^{(1)} + 2 \sigma_{1x} \right) z_{t+K-1}
\]

Since each summand in the above expressions is a scalar we are free to replace any component with its transpose. This will enable us to gather terms on \( z_{t+K-1} \) and \( z_{t+K-1} \). Substituting these expressions into the \((t+K-1)\) objective leads to an expression which takes the form of an expectation of an exponential polynomial of the state vector and can be solved in closed form to yield the maximized value function:

\[
E_{t+K-1} \left[ \exp \left\{ (1 - \gamma) r_{p,t+K} \right\} \right] = \exp \left\{ (1 - \gamma) \left( B_0^{(1)} + B_1^{(1)} z_{t+K-1} + z_{t+K-1} B_2^{(1)} z_{t+K-1} \right) \right\}
\]

(35)

where:

\[
B_0^{(1)} \equiv \Phi_1^1 + A_0^{(1)'} \left( \Phi_0^1 + \frac{1}{2} \sigma_x^2 \right) + \frac{1}{2} \left( \sigma_x^2 \Phi_0^1 + 2 A_0^{(1)'} \sigma_{1x} \right) - \frac{1}{2} A_0^{(1)'} \Sigma_{xx} A_0^{(1)}
\]

(36)

\[
B_1^{(1)} \equiv \Phi_1^1 + A_0^{(1)'} \left( \Phi_1^1 - \gamma \Sigma_{xx} A_1^{(1)} \right) + \left( \Phi_0^1 + \frac{1}{2} \sigma_x^2 + (1 - \gamma) \sigma_{1x} \right) A_1^{(1)}
\]

(37)

\[
B_2^{(1)} \equiv A_1^{(1)'} \left( \Phi_1^1 - \frac{\gamma}{2} \Sigma_{xx} A_1^{(1)} \right)
\]

(38)

In order to retain the generality of the formulae we refrain from substituting in period specific values for the coefficients of the optimal portfolio (e.g. \( A_0^{(1)} \) and \( A_1^{(1)} \)). By establishing the general form of the relationship between the value and policy function coefficients in adjacent periods we will be able to adapt the solution to a general multi-period setting without having to do any additional derivations.
B.2 **Time** \( t + K - 2 \ (\tau = 2) \)

### B.2.1 Policy function

The \( t + K - 2 \) problem involves the choice of the portfolio \( \alpha_{t+K-2}^{(2)} \) which maximizes the following objective:

\[
\frac{W_{t+K-2}^{1-\gamma}}{1-\gamma} E_{t+K-2} \left[ \exp \left\{ (1-\gamma) r_{p,t+K-1} \right\} \exp \left\{ (1-\gamma) \left( B_{0}^{(1)} + B_{1}^{(1)} z_{t+K-1} + z_{t+K-1} B_{2}^{(1)} \right) \right\} \right]
\]

Since the prefactor involving \( W_{t+K-2} \) and \( \gamma \) does not affect the optimization problem, we drop it in subsequent expressions in order to economize on notation. We begin the derivation of the optimal policy function by making use of the Campbell-Viceira approximation to express the time \( t + K - 1 \) log portfolio return in terms of the \( z_{t+K-1} \). This allows us to collect terms in the exponential and compute its expectation.

The \( t + K - 1 \) log portfolio return can be approximated by:

\[
r_{p,t+K-1} = \alpha_{t+K-2}^{(2)'} x_{t+K-1} + r_{1,t+K-1} + \frac{1}{2} \alpha_{t+K-2}^{(2)'} \left( \sigma_{x} - \Sigma_{xx} \alpha_{t+K-2}^{(2)} \right)
\]

which - after substituting into the objective function and dropping the prefactor - yields:

\[
E_{t+K-2} \left[ \exp \left\{ (1-\gamma) \left( \frac{1}{2} \alpha_{t+K-2}^{(2)'} \left( \sigma_{x} - \Sigma_{xx} \alpha_{t+K-2}^{(2)} \right) + B_{0}^{(1)} + \left[ 1 \ \alpha_{t+K-2}^{(2)} 0 \right] z_{t+K-1} + z_{t+K-1} B_{2}^{(1)} \right) \right\} \right]
\]

From the point of view of the investor at time \( t + K - 2 \) only the last two summands in the exponential are random. The computation of the expectation can therefore be simplified by focusing on the random components. We therefore focus on evaluating the following expression given the investor’s choice of \( \alpha_{t+K-2}^{(2)} \):

\[
E_{t+K-2} \left[ \exp \left\{ (1-\gamma) \left( B_{1}^{(1)} + \left[ 1 \ \alpha_{t+K-2}^{(2)} 0 \right] z_{t+K-1} + z_{t+K-1} B_{2}^{(1)} \right) \right\} \right]
\]

The result of this computation is then substituted back into (40) to obtain the expectation of the value function conditional on the investor’s portfolio choice decision, which is then maximized over \( \alpha_{t+K-2}^{(2)} \).

Since the distribution of \( z_{t+K-1} \) conditional on time \( t + K - 2 \) information is:

\[
z_{t+K-1|t+K-2} \sim N (\Phi_{0} + \Phi_{z} z_{t+K-2}, \Sigma_{\nu})
\]

it is clear that the evaluation of (41) is tantamount to computing the expectation of an exponential of a quadratic polynomial in a normal random variable. We can proceed from here in one of two ways depending on whether we use the continuous time approximation to (41) or not. We present the solutions for both scenarios, but we elect to focus on the continuous-time approximation since this approach is complementary to the continuous-time approximation to the portfolio return used throughout the paper.

---

38
In order economize on space we first introduce the following notation:

\[
C_1^{(2)} = (1 - \gamma) \begin{bmatrix} \alpha_{t+K-2}^{(2)} \\ 0 \end{bmatrix} + (1 - \gamma) D_i^{(2)}
\]

\[
C_2^{(2)} = (1 - \gamma) B_i^{(2)}
\]

which, when combined with the conditional distribution of \(z_{t+K-1} + z_{t+K-1} C_{t+K-1} - z_{t+K-1}\), allows us to re-express (41) as:

\[
E_{t+K-2} \left[ \exp \left( C_1^{(2)} z_{t+K-1} + z_{t+K-1} C_2^{(2)} z_{t+K-1} \right) \right] = E_{t+K-2} \left[ \exp \left( C_1^{(2)} (\Phi_0 + \Phi_1 z_{t+K-2} + v_{t+K-2}) + (\Phi_0 + \Phi_1 z_{t+K-2} + v_{t+K-2}) \right) \right]
\]

Inspection of this equation makes immediately clear that the terms appearing in the exponential are either constants, linear combinations of the \(v_{t+K-2}\) shocks or quadratic forms in \(v_{t+K-2}\) (i.e. the term \(v_{t+K-2} C_2^{(2)} v_{t+K-2}\)). We can further reorder the terms in equation (42) as follows:

\[
E_{t+K-2} \left[ \exp (\cdot) \right] = \exp \left( C_1^{(2)} (\Phi_0 + \Phi_1 z_{t+K-2}) + (\Phi_0 + \Phi_1 z_{t+K-2}) C_2^{(2)} (\Phi_0 + \Phi_1 z_{t+K-2}) \right)
\]

\[
\times E_{t+K-2} \left[ \exp \left( C_1^{(2)} v_{t+K-2} + v_{t+K-2} C_2^{(2)} (\Phi_0 + \Phi_1 z_{t+K-2}) + (\Phi_0 + \Phi_1 z_{t+K-2}) C_2^{(2)} v_{t+K-2} \right) \right]
\]

\[
= \exp \left( C_1^{(2)} (\Phi_0 + \Phi_1 z_{t+K-2}) + (\Phi_0 + \Phi_1 z_{t+K-2}) C_2^{(2)} (\Phi_0 + \Phi_1 z_{t+K-2}) \right)
\]

\[
\times E_{t+K-2} \left[ \exp \left( C_1^{(2)} v_{t+K-2} + v_{t+K-2} C_2^{(2)} (\Phi_0 + \Phi_1 z_{t+K-2}) + (\Phi_0 + \Phi_1 z_{t+K-2}) C_2^{(2)} v_{t+K-2} \right) \right]
\]

\[
= \exp \left( C_1^{(2)} (\Phi_0 + \Phi_1 z_{t+K-2}) + (\Phi_0 + \Phi_1 z_{t+K-2}) C_2^{(2)} (\Phi_0 + \Phi_1 z_{t+K-2}) \right)
\]

\[
\times E_{t+K-2} \left[ \exp \left( v_{t+K-2} C_2^{(2)} v_{t+K-2} \right) \right] \times \exp \left( \left( C_1^{(2)} + 2 (\Phi_0 + \Phi_1 z_{t+K-2}) C_2^{(2)} v_{t+K-2} \right) \right),
\]

where we have introduced the convention that any matrix annotated with a tilde is to be interpreted as the average of the non-tilde matrix and its transpose. For example:

\[
\tilde{C}_2^{(2)} = \frac{1}{2} (C_2^{(2)} + C_2^{(2) \\
}\)

Clearly, all such matrices are symmetric by construction. The tilde convention is introduced to ensure that the validity of our results does not hinge on the symmetry of the underlying matrices - in this case \(C_2^{(2)}\). However, whenever we show that the underlying matrix is symmetric we drop the tilde notation to avoid redundancy since in those cases the underlying-matrix and the tilde-matrix are identical.

There are two approaches that we can adopt to evaluate the expectation operator in equation (43). First, we can introduce an additional approximation which is exact in continuous time and - in this sense - complements the portfolio return approximation; second, we can simply evaluate the expectation by “completing the square” of the expression in the exponential, following CCV (2003). We present both results for completeness even though they provide empirically indistinguishable results with return data measured at the monthly frequency.

**Complementary approximation**

We begin by presenting the complementary approximation, which we utilize to obtain the value of the first expectation. To arrive at our result we simply rely on the fact that all terms of order exceeding \(dt\) have vanishing probability limits as the
time interval shrinks to zero. Thus in the limit of continuous time, only the linear terms in equation (43) remain random. More precisely, the linear terms are of order $dZ$, while the quadratic terms are of order $dt$ (i.e. asymptotically they are deterministic). Thus
\[
\lim_{\Delta t \to 0} \exp \left\{ \mathbf{v}'_{t+K-2} C_2^{(2)} \mathbf{v}_{t+K-2} \right\} / dt = \exp \left\{ \operatorname{tr}(C_2^{(2)} \mathbf{v}_{t}) \right\},
\]
and equation (43) becomes
\[
\exp \left\{ C_1^{(2)'} \left( \Phi_0 + \Phi_1 \mathbf{z}_{t+K-2} \right) + \left( \Phi_0 + \Phi_1 \mathbf{z}_{t+K-2} \right)' C_2^{(2)} \left( \Phi_0 + \Phi_1 \mathbf{z}_{t+K-2} \right) \right\}
\times E_{t+K-2} \left[ \exp \left\{ \left( C_1^{(2)'} + 2 \left( \Phi_0 + \Phi_1 \mathbf{z}_{t+K-2} \right)' C_2^{(1)} \right) \mathbf{v}_{t+K-2} \right\} \right]
\]
(44)

Fortunately, the expectation in (44) is nothing more than an expectation of a log-normal random variable, and is given by
\[
E_{t+K-2} \left[ \exp \left\{ \left( C_1^{(2)'} + 2 \left( \Phi_0 + \Phi_1 \mathbf{z}_{t+K-2} \right)' C_2^{(1)} \right) \mathbf{v}_{t+K-2} \right\} \right] = \exp \left\{ \frac{1}{2} \left( \mathbf{C}_1^{(2)'} + 2 \left( \Phi_0 + \Phi_1 \mathbf{z}_{t+K-2} \right)' C_2^{(1)} \right) \mathbf{C}_1^{(2)} \right\}
\]
(45)

Combining (44) and (45) we see that in the continuous-time limit (41) is equal to:
\[
\lim_{\Delta t \to 0} E_{t+K-2} \left[ \exp \left\{ \mathbf{C}_1^{(2)'} \mathbf{z}_{t+K-1} + \mathbf{z}'_{t+K-1} C_2^{(2)} \mathbf{z}_{t+K-1} \right\} \right] = \exp \left\{ \operatorname{tr}(C_2^{(2)} \mathbf{v}_{t}) + \mathbf{D}_0^{(t+K-2)} + \frac{1}{2} \mathbf{D}_1^{(t+K-2)} \mathbf{v}_{t} \right\}
\]
(46)

where
\[
\mathbf{D}_0^{(2)} = \mathbf{C}_1^{(2)'} \left( \Phi_0 + \Phi_1 \mathbf{z}_{t+K-2} \right) + \left( \Phi_0 + \Phi_1 \mathbf{z}_{t+K-2} \right)' C_2^{(2)} \left( \Phi_0 + \Phi_1 \mathbf{z}_{t+K-2} \right)
\]
\[
\mathbf{D}_1^{(2)} = \mathbf{C}_1^{(2)'} + 2 \left( \Phi_0 + \Phi_1 \mathbf{z}_{t+K-2} \right)' C_2^{(1)}.
\]

**Exact evaluation**

Had we elected not to rely on the continuous-time approximation to the exponential quadratic term a closed-form solution would still be available. In particular, the results derived in CCV (2003) provide a direct route to the computing the expectation in (41). Using the previously introduced notation we can apply equation (46) from the technical appendix to CCV (2003) to arrive at the following expression:
\[
E_{t+K-2} \left[ \exp \left\{ \mathbf{C}_1^{(2)'} \mathbf{z}_{t+K-1} + \mathbf{z}'_{t+K-1} C_2^{(2)} \mathbf{z}_{t+K-1} \right\} \right] = \frac{\mathbf{\Sigma}^{(1)}}{\left( \mathbf{\Sigma}^{-1} - 2 \mathbf{D}_2^{(t+K-2)} \right)^{\frac{1}{2}}} \exp \left( \mathbf{D}_0^{(t+K-2)} + \frac{1}{2} \mathbf{D}_1^{(t+K-2)} \mathbf{\Omega}^{(1)} \mathbf{D}_1^{(t+K-2)'} \right)
\]
(47)

where we have additionally introduced $\mathbf{D}_2^{(2)} = \mathbf{C}_2^{(2)}$ and
\[
\mathbf{\Omega}^{(1)} \equiv \left( \mathbf{\Sigma}^{-1} - 2 \mathbf{D}_2^{(2)} \right)^{-1} = \left( \mathbf{\Sigma}^{-1} - 2(1-\gamma)\mathbf{B}_2^{(1)} \right)^{-1}.
\]
(48)

The similarities and differences between equation (46) and equation (47) are immediate.

**Optimal portfolio policy**

With (46) or (47) in hand, we can replace the (conditional) expectation of the random component of the value function, (41), with a function that only depends on $\mathbf{\alpha}^{(2)}_{t+K-2}$ and the time $(t+K-2)$ state vector. Since equations (46) and (47) are functionally identical, the derivation and the form of the solution under each is identical—and numerically indistinguishable in our empirical calibration exercise with return data measured at the monthly frequency. We now derive the solution implied
by (47), and state the solution implied by (46).

To derive the optimal portfolio rule, we economize on notation by dropping the prefactor arising from the computation of the expectation of the exponential polynomial (47), since constant prefactors do not affect the solution to the maximization problem. This allows us to reformulate the problem facing the investor at time \( t + K - 2 \) as:

\[
\max_{\alpha_{t+K-2}} \left\{ (1 - \gamma) \left( \frac{1}{2} \alpha_{t+K-2}^{(2)} \left( \sigma_x^2 - \Sigma_{xx} \alpha_{t+K-2}^{(2)} + B_0 + D_0^{(t+K-2)} \sigma_x^2 \right) + D_1^{(t+K-2)} \right) \right\}
\]

Taking first derivatives with respect to the vector of portfolio weights we arrive at the following first order condition for \( \alpha_{t+K-2}^{(2)} \):

\[
0 = (1 - \gamma) \left( \Phi_0^{(2)} + \Phi_2 \sigma_{zt+K-2} + \frac{1}{2} \sigma_x^2 \Sigma_{xx} \alpha_{t+K-2}^{(2)} + B_0 + \frac{1}{2} \left( \frac{\partial D_1^{(t+K-2)}}{\partial \alpha_{t+K-2}} \right)^2 \left( \Omega^{(2)} + \Omega^{(1)} \right) D_1^{(t+K-2)} \right)
\]

Given the definition for \( D_1^{(2)} \), we can relate its derivative with respect to the portfolio allocation to the risky asset excess return selector matrix (i.e. the selector matrix which returns the rows denoted by \( x \)):

\[
\frac{\partial D_1^{(t+K-2)}}{\partial \alpha_{t+K-2}} = (1 - \gamma) \left[ \begin{array}{c} 0 \\ I_{n-1} \\ 0 \end{array} \right] = (1 - \gamma) \mathbf{H}_x
\]

This ultimately leads us to the following form of the first order condition:

\[
0 = \Phi_0^{(2)} + \Phi_2 \sigma_{zt+K-2} + \frac{1}{2} \sigma_x^2 \Sigma_{xx} \alpha_{t+K-2}^{(2)} + \mathbf{H}_x \Omega^{(1)} \left( \sigma_x^2 + 2 \tilde{C}_2 \left( \Phi_0 + \Phi_2 \sigma_{zt+K-2} \right) \right)
\]

Solving the first order condition yields an expression for the optimal portfolio holding at time \( t + K - 2 \) in the form of an affine function of \( z_{t+K-2} \):

\[
\alpha_{t+K-2}^{(2)} = A_0^{(2)} + A_1^{(2)} z_{t+K-2}
\]

where:

\[
A_0^{(2)} = \left( \Sigma_{xx} - (1 - \gamma) \Omega_x^{(1)} \right)^{-1} \left( \Phi_0^{(2)} + \frac{1}{2} \sigma_x^2 + (1 - \gamma) \left( \Omega_x^{(1)} + \Omega_x^{(2)} \left( B_1^{(1)} + 2 \tilde{B}_2 \Phi_0 \right) \right) \right)
\]

\[
A_1^{(2)} = \left( \Sigma_{xx} - (1 - \gamma) \Omega_x^{(1)} \right)^{-1} \left( \Phi_1^{(2)} + 2(1 - \gamma) \tilde{\Omega}_x^{(1)} \tilde{B}_2 \Phi_1 \right)
\]

31 While dropping the prefactors arising from the evaluation of the expectation does not affect the choice of the optimal portfolio, it will affect the value function for the problem. By keeping track of these prefactors it is possible to derive a closed-form expression for the value function, and consequently, conduct an extensive welfare analysis.
Similar computations based on (46) lead to the following expression:

\[
A^{(2)}_0 = \frac{1}{\gamma} \sum_{x} \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 + (1 - \gamma) \left( \sum_{x} + \sum_x \left( B^{(1)'}_1 + 2 \tilde{B}^{(2)}_2 \Phi_0 \right) \right) \right)
\]

\[
A^{(2)}_1 = \frac{1}{\gamma} \sum_{x} \left( \Phi_1^x + 2(1 - \gamma) \sum_x \tilde{B}^{(1)}_2 \Phi_1 \right)
\]

It is important to note that (52) and (53) are identical to (50) and (51), except that \( \tilde{\Omega} \) is replaced with \( \Sigma_x \).

### B.2.2 Value function

In order to complete the derivation of the general recursive solution we still need to develop the relevant expressions for the coefficients in the maximized value function, \( B^{(2)}_i \). This will enable us to determine the relationship with the preceding values of the \( A^{(2)}_i \) and \( B^{(1)}_i \) coefficients. Substituting the optimal portfolio allocation for \( t + K - 2 \) into the value function, (39), and omitting any prefactors multiplying the expectation we obtain:

\[
E_{t+K-2} \left[ \exp \left\{ (1 - \gamma) r_{p,t+K-1} \right\} \exp \left\{ (1 - \gamma) \left( B^{(1)}_0 + B^{(1)}_1 \sum_{t+K-1} B^{(2)}_1 \sum_{t+K-1} \right) \right\} \right] =
\]

\[
\exp \left\{ (1 - \gamma) \left( \frac{1}{2} \sigma_{t+K-2}^2 + B_0^{(1)} + B_1^{(1)} \sum_{t+K-2} + B_0^{(2)} + B_1^{(2)} \sum_{t+K-2} + B_2^{(2)} \sum_{t+K-2} \right) \right\}
\]

where:

\[
B^{(2)}_0 = \Phi_0^x + A^{(1)'}_0 \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 \right) + \frac{1}{2} \left( \sum_{x} + \sum_x \left( B_0^{(1)} + B_1^{(1)} \sum_{t+K-2} + B_0^{(2)} + B_1^{(2)} \sum_{t+K-2} + B_2^{(2)} \sum_{t+K-2} \right) \right) -
\]

\[
- \frac{1}{2} A^{(1)'}_0 \left( \sum_{x} + (1 - \gamma) \sum_{x} B^{(1)}_1 \sum_{t+K-2} A^{(1)}_0 + B^{(1)}_0 + B^{(1)}_1 + \Phi_0^x B^{(2)}_2 \right) \Phi_0 +
\]

\[
+ (1 - \gamma) B^{(1)}_1 \left( \sum_{x} + (1 - \gamma) \sum_{x} + \sum_x \sum_{t+K-2} \sum_{t+K-2} + \sum_{x} \sum_{t+K-2} \sum_{t+K-2} \right) \Phi_0 +
\]

\[
B^{(2)}_1 = \Phi_1^x + A^{(1)'}_0 \left( \Phi_1^x - \left( \sum_{x} + (1 - \gamma) \sum_{x} B^{(2)}_2 \right) A^{(1)}_0 \right) + \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 + (1 - \gamma) \sum_{x} \right) A^{(1)}_0 +
\]

\[
+ \left( B_0^{(1)} + B_1^{(1)} \sum_{t+K-2} + B_2^{(2)} \sum_{t+K-2} \right) \Phi_1 +
\]

\[
B^{(2)}_2 = A^{(1)'}_1 \left( \Phi_1^x - \frac{1}{2} \left( \sum_{x} + (1 - \gamma) \sum_{x} B^{(2)}_2 \right) A^{(1)}_0 \right) + \Phi_1 \left( B_0^{(1)} + B_1^{(1)} \sum_{t+K-2} + B_2^{(2)} \sum_{t+K-2} \right)
\]

where we have defined the auxiliary matrices \( \Lambda^{(1)} = \tilde{B}^{(1)}_2 \sum_{t+K-2} \sum_{t+K-2} + \sum_{x} \sum_{t+K-2} \sum_{t+K-2} \right) \Phi_1 +
\]

\[
+ (1 - \gamma) \Phi_1 \sum_{x} \sum_{t+K-2} \sum_{t+K-2} \right) \Phi_1 +
\]

\[
\text{where we have defined the auxiliary matrices } \Lambda^{(1)} = \tilde{B}^{(1)}_2 \sum_{t+K-2} \sum_{t+K-2} + \sum_{x} \sum_{t+K-2} \sum_{t+K-2} \right) \Phi_1 +
\]

\[
\text{In the limit of continuous-time we obtain a set of simplifications analogous to those appearing in the derivation of the policy function. In particular, making the relevant substitutions we find the following expressions for the value function}
\]

42
coefficients:

\[
B_0^{(2)} = \Phi_0 + A_0^{(1)'} \left( \Phi_0^* + \frac{1}{2} \sigma_x^2 \right) + \frac{1 - \gamma}{2} \left( \Sigma_{11} + 2 A_0^{(1)'} \Sigma_{1x} \right) - \frac{\gamma}{2} A_0^{(1)'} \Sigma_{x} A_0^{(1)} + B_0^{(1)} + \left( B_0^{(1)} + \Phi_0 B_2^{(1)} \right) \Phi_0 + \left( 1 - \gamma \right) B_1^{(1)} \left( \Sigma_1 + \frac{1}{2} \Sigma B_1^{(1)} + \Sigma_{1} A_0^{(1)} \right) + \left( 1 - \gamma \right) \Phi_0^* \left( 2 \Lambda^{(1)} A_0 + \Xi^{(1)'} + \Xi^{(1)'} A_0^{(1)} + \Gamma^{(1)} B_1^{(1)} \right)
\]

\[
B_1^{(2)} = \Phi_1 + A_0^{(1)'} \left( \Phi_1 - \gamma \Sigma_{x} \right) A_0^{(1)} + \left( \Phi_0 + \frac{1}{2} \sigma_x^2 \right) A_0^{(1)} + \left( B_1^{(1)} + 2 \Phi_0 B_2^{(1)} \right) \Phi_1 + \left( 1 - \gamma \right) \left( B_1^{(1)} \Sigma_{x} \Phi_0 + \Phi_0 \Xi^{(1)'} \right) A_0^{(1)} + \left( 1 - \gamma \right) \left( 4 \Phi_0 \Lambda^{(1)} + \Xi^{(1)} + A_0^{(1)'} \Xi_{x} + B_1^{(1)} \Xi^{(1)} \right) \Phi_1
\]

\[
B_2^{(2)} = A_0^{(1)'} \left( \Phi_1^* - \frac{1}{2} \Sigma_{xx} A_1^{(1)} \right) + \Phi_1 \left( B_1^{(1)} + 2 (1 - \gamma) \Lambda^{(1)} \right) \Phi_1 + (1 - \gamma) \Phi_1^* \Xi^{(1)'} A_1^{(1)}
\]

where we have defined the auxiliary matrices \( \Lambda^{(1)} = \tilde{B}_2^{(1)} \Sigma_{x} \tilde{B}_2^{(1)} \), \( \Gamma^{(1)} = 2 \tilde{B}_2^{(1)} \Sigma_{x} \) and \( \Xi^{(1)} = \Gamma^{(1)'} \).

### B.2.3 The general recursive solution

Since we have refrained from substituting any period specific values in the derivation of the time \((t + K - 2)\) formulas of the policy and value function coefficients, the results of the previous section provide the complete characterization of the link between the policy and value functions in any two adjacent periods. In other words, the link between the coefficients governing policy and value functions in periods \((\tau)\) and \((\tau - 1)\), is exactly the same as the link between periods \((2)\) and \((1)\). Therefore the general recursive solution is obtained simply by making the following replacements:

\[
(1) \rightarrow (\tau - 1) \quad \text{and} \quad (2) \rightarrow (\tau)
\]

in the recursive formulas for the policy function (eqs. (50) and (51)) and value function coefficients (eqs. (55), (56) and (57)). The base cases for the recursions in the policy and value function coefficients are given by, (eqs. (33) and (34)) and (eqs. (36), (37) and (38)), respectively. These two sets of recursions, along with their base cases, provide a complete characterization of the optimal dynamically consistent portfolio policy.

### B.2.4 Matrix symmetry

Having derived the general solution we now check whether any further simplification is possible as a result of the symmetry of the matrices in the policy and value function recursions. In particular, throughout the derivations we used the tilde convention to assure that our results would be robust to any underlying matrix non-symmetries. Here we verify that the tilde notation can indeed be dropped.

The matrices which were affected by the tilde notation are \( B_2^{(r)} \), \( C_2^{(r)} \) and \( \Omega^{(1)} \). However, as can be seen directly from the derivation the second two matrices are merely transformations of the corresponding \( B_2^{(r)} \) matrices. Therefore if we can ascertain that \( B_2^{(r)} \) is symmetric then so will \( C_2^{(r)} \) and \( \Omega^{(1)} \). In order to ascertain this fact we need to show that \( B_2^{(1)} \) is symmetric and the recursion relating \( B_2^{(r)} \) to \( B_2^{(r-1)} \) preserves this symmetry. The first fact is readily established since:

\[
B_2^{(1)} = A_1^{(1)'} \left( \Phi_1^* - \frac{1}{2} \Sigma_{xx} A_1^{(1)} \right) = \frac{1}{2 \gamma} \Phi_1^* \Sigma_{xx} \Phi_1^*
\]

which is clearly symmetric.
B.3 Special cases

To gain additional intuition regarding the solution and to confirm its validity we examine two corner cases: $\gamma = 1$ and $\gamma \to \infty$. Below we present the simplified forms of the base cases and recursive relationships:

1. **Myopic portfolio choice.** Substituting in $\gamma = 1$ into the general relationships derived in the previous two sections results in the following expressions. The portfolio choice policy coefficients evolve according to:

\[
A_0^{(\tau)} = \Sigma_{xz}^{-1} \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 \right) \quad \forall \tau
\]

\[
A_1^{(\tau)} = \Sigma_{xz}^{-1} \Phi_1^x \quad \forall \tau
\]

since:

\[
\Omega^{(1)} = \Sigma_{xv} \quad \forall \tau
\]

Consequently, the base case for the policy function recursion becomes:

\[
B_0^{(1)} = \Phi_0^1 + A_0^{(1)\prime} \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 - \frac{1}{2} \Sigma_{xx} A_1^{(1)} \right) = \Phi_0^1
\]

\[
B_1^{(1)} = \Phi_1^1 + A_0^{(1)\prime} \left( \Phi_1^x - \Sigma_{xx} A_1^{(1)} \right) + \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 \right)^\prime A_1^{(1)} = \Phi_1^1 + \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 \right)^\prime \Sigma_{xx} \Phi_1^x
\]

\[
B_2^{(1)} = A_1^{(1)\prime} \left( \Phi_1^x - \frac{1}{2} \Sigma_{xx} A_1^{(1)} \right) = \frac{1}{2} \Phi_1^\prime \Sigma_{xx}^{-1} \Phi_1^x
\]

and the recursive relationship itself is given by:

\[
B_0^{(\tau)} = \Phi_0^1 + A_0^{(1)\prime} \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 - \frac{1}{2} \Sigma_{xx} A_1^{(\tau-1)} \right) + B_0^{(\tau-1)} + \left( B_1^{(\tau-1)} + \Phi_0^1 B_2^{(\tau-1)} \right) \Phi_0
\]

\[
= \Phi_0^1 + \frac{1}{2} \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 \right)^\prime \Sigma_{xx}^{-1} \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 \right) + B_0^{(\tau-1)} + \left( B_1^{(\tau-1)} + \Phi_0^1 B_2^{(\tau-1)} \right) \Phi_0
\]

\[
B_1^{(\tau)} = \Phi_1^1 + A_0^{(\tau-1)\prime} \left( \Phi_1^x - \Sigma_{xx} A_1^{(\tau-1)} \right) + \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 \right)^\prime A_1^{(\tau-1)} + \left( B_1^{(\tau-1)} + 2 \Phi_0^1 B_2^{(\tau-1)} \right) \Phi_1
\]

\[
= \Phi_1^1 + \left( \Phi_0^x + \frac{1}{2} \sigma_x^2 \right)^\prime \Sigma_{xx}^{-1} \Phi_1^x + \left( B_1^{(\tau-1)} + 2 \Phi_0^1 B_2^{(\tau-1)} \right) \Phi_1
\]

\[
B_2^{(\tau)} = A_1^{(\tau-1)\prime} \left( \Phi_1^x - \frac{1}{2} \Sigma_{xx} A_1^{(\tau-1)} \right) + \Phi_1^\prime B_2^{(\tau-1)} \Phi_1 = \frac{1}{2} \Phi_1^\prime \Sigma_{xx}^{-1} \Phi_1^x + \Phi_1^\prime B_2^{(\tau-1)} \Phi_1
\]

2. **Infinite risk aversion** ($\gamma \to \infty$). In order to examine the asymptotic behavior of the recursive relationships determining portfolio choice it is useful to first focus on the order of the terms in $\gamma$, $O(\gamma^{-n})$. Terms for which $n \geq 1$ will disappear in the limit, those with $n = 0$ will yield constants, and those with $n < 0$ will diverge. Intuitively, we expect that while terms in the value function recursion may diverge those in the portfolio policy functions will not. Since the value function is an exponential polynomial function, divergence to negative infinity is permissible as it indicates that the value of the problem tends to zero.

We begin with the base case for the policy function recursion. It is immediate that the terms, $A_0^{(1)}$, and $A_1^{(1)}$, are of order $O(1)$ and $O(\gamma^{-1})$. In particular we obtain the following limits:

\[
A_0^{(1)} \to -\Sigma_{xz}^{-1} \sigma_{xx} \quad A_1^{(1)} \to 0
\]

A similar examination for the base case of the policy function recursion reveals that, $B_0^{(1)}$ has order $O(\gamma)$ and diverges...
to negative infinity, $B_1^{(1)}$ has order $O(1)$ and converges to:

$$B_1^{(1)} \to \Phi_1 - \sigma_{x1} \Sigma_{x2}^{-1} \Phi_1$$

Lastly, $B_2^{(1)}$ is of order $O(\gamma^{-1})$ and hence converges to zero. With these results we can infer that $\Omega^{(1)}$ will be $O(1)$ in the coefficient of risk aversion and, consequently, each iteration will lead to a non-negligible adjustment to the covariance matrix of the shocks. In particular we have that:

$$\Omega^{(1)} \to \left( \Sigma_{x1}^{-1} + \Phi_1' \Sigma_{x2}^{-1} \Phi_1 \right)^{-1}$$

Next we proceed to the $t + K - 2$ policy function coefficients. To make the analysis easier to interpret we can write the expressions in the following form:

$$A_0^{(2)} = \left( \frac{1}{\gamma} \Sigma_{xx} - \left( \frac{1}{\gamma} - 1 \right) \Omega_{xx}^{(1)} \right)^{-1} \left( \frac{1}{\gamma} \Phi_0 + \frac{1}{2\gamma} \sigma_x^2 + \left( \frac{1}{\gamma} - 1 \right) \Omega_{x1}^{(1)} + \Omega_{x2}^{(1)} (B_1^{(1)'}) \Phi_0 \right)$$

$$A_1^{(2)} = \left( \frac{1}{\gamma} \Sigma_{xx} - \left( \frac{1}{\gamma} - 1 \right) \Omega_{xx}^{(1)} \right)^{-1} \left( \frac{1}{\gamma} \Phi_1 + 2 \left( \frac{1}{\gamma} - 1 \right) \Omega_{x1}^{(1)} B_1^{(1)} \Phi_1 \right)$$

Taking limits and noting the previously derived orders of the constituent terms leads to:

$$A_0^{(2)} \to - \left( \Omega_{xx}^{(1)} \right)^{-1} \left( \Omega_{x1}^{(1)} + \Omega_{x2}^{(1)} B_1^{(1)'}) \right)$$

$$A_1^{(2)} \to 0$$

Continuing in this fashion it is possible to show that the order of each of the terms appearing in the solution is conserved under the recursion, and therefore, that the results we just derived apply to all time periods. In particular - with a slight abuse of limit notation - the recursion for the value function coefficients truncates to:

$$B_0^{(2)} \to -\infty$$

$$B_1^{(2)} \to \Phi_1 + A_0^{(1)'} \Phi_1^* + B_1^{(1)'} \Phi_1 - \gamma B_1^{(1)} \Omega_{xx}^{(1)} A_1^{(1)} - \gamma (\Xi_{x1}^{(1)} + A_1^{(1)' \Xi_{x2}^{(1)} + B_1^{(1) \Xi_{x1}^{(1)}}} \Phi_1$$

$$B_2^{(2)} \to 0$$

In particular, although some expressions continue to have $\gamma$ in them they are $O(1)$ due to the presence of offsetting terms that are $O(\gamma^{-1})$, which are not fully expanded. For completeness we note that in arriving at these simplified expressions we have made use of the fact that $A^{(1)} \sim O(\gamma^{-2})$, $\Gamma^{(1)} \sim O(\gamma^{-1})$ and $\Xi^{(1)} \sim O(\gamma^{-1})$, and hence all converge to zero as $\gamma$ diverges.

Consequently, it is clear that as the agent becomes infinitely risk averse the policy function becomes decoupled from the intercept vector, $\Phi_0$, of the vector autoregressive model. This result is similar to the optimal portfolio allocation of an infinitely risk averse investor maximizing a mean-variance objective based on K-period moments. In fact, the portfolio allocation at $t + K - 1$ is precisely the global minimum variance portfolio for the one-period problem.

3. **No Predictability ($\Phi_1 = 0$)** When returns are unpredictable the slope matrix of the VAR(1) model is identically equal to zero. In this case the first period policy function coefficients truncate to:

$$A_0^{(1)} = \frac{1}{\gamma} \Sigma_{xx}^{-1} \left( \Phi_0 + \frac{1}{2\gamma} \sigma_x^2 + (1 - \gamma) \sigma_{xz} \right)$$

$$A_1^{(1)} = 0$$
and lead to the following set of coefficients for the base case of the value function recursion:

\[
\begin{align*}
B_0^{(1)} &= \Phi_0^1 + A_0^{(1)'} \left( \Phi_0^0 + \frac{1}{2} \sigma_2^2 \right) + \frac{1}{2} \left( \frac{1}{2} (\sigma_1^2 + 2 A_0^{(1)'} \sigma_{1x}) - \frac{\gamma}{2} A_0^{(1)'} \Sigma_{xx} A_0^{(1)} \right) \\
B_1^{(1)} &= B_2^{(1)} = 0
\end{align*}
\]

Consequently, it is easy to see that we have \( \Omega^{(1)} = \Sigma \), which, along with the values of the value function coefficients, yields:

\[
A_0^{(2)} = A_0^{(1)} \quad A_1^{(2)} = A_0^{(1)}
\]

Continuing, by substituting these values into the time (2) value function coefficients leads to:

\[
\begin{align*}
B_0^{(2)} &= \Phi_0^1 + A_0^{(1)'} \left( \Phi_0^0 + \frac{1}{2} \sigma_2^2 \right) + \frac{1}{2} \left( \frac{1}{2} (\sigma_1^2 + 2 A_0^{(1)'} \sigma_{1x}) - \frac{\gamma}{2} A_0^{(1)'} \Sigma_{xx} A_0^{(1)} + B_0^{(1)} \right) \\
B_1^{(2)} &= B_2^{(2)} = 0
\end{align*}
\]

since \( A^{(1)} = \Gamma^{(1)} = \Xi^{(1)} = 0 \). Given that the portfolio rule is only affected by the \( B_1 \) and \( B_2 \) matrices and the fact that the value of these two matrices only depends on their own lagged values and the lagged value of \( A_1 \), one can immediately conclude that the portfolio allocation is constant across time and uniquely determined by \( A_0 \). The value of the problem, on the other hand, is determined by \( B_0 \).
C Appendix: Temporal Aggregation of the VAR(1) model

The VAR(1) class of time-series models is closed under temporal aggregation. In other words, if \( z_{t+1} \) follows an VAR(1) process, so will \( \sum_{i=0}^{n} s_{t+1+i} \). This observation enables us to interpret our model as applying at different data frequencies, and consequently, allows us to examine the effect of the re-balancing frequency on the agent’s welfare.

Consider the constrained version of the VAR(1) model in which the state variables forecast themselves and returns, but the returns are forecast only by the state variables and do not have any forecasting power themselves. This system is equivalent to the system of equations:

\[
\begin{align*}
r_{t+1} & = \Phi_{0r} + \Phi_{1r} s_t + v_{r,t+1} \\
 s_{t+1} & = \Phi_{0s} + \Phi_{1s} s_t + v_{s,t+1} \\
\end{align*}
\]

The covariance matrix of the shocks to the constrained system can be decomposed into three matrices, \( \Sigma_{rr}, \Sigma_{rs} \) and \( \Sigma_{ss} \).

Now consider forecasting k-period returns at time \( t \) using the time \( t \) values of the state variables. A simple recursion indicates that:

\[
\sum_{i=0}^{k-1} r_{t+i} = k \cdot \Phi_{0r} + \Phi_{1r} \sum_{j=0}^{k-1} s_{t+j} + \sum_{j=0}^{k-1} v_{r,t+j+1} \equiv \tilde{r}_{t+k}
\]

\[
s_{t+k} = \left( \sum_{i=0}^{k-1} \Phi_{1s} \right) \cdot \Phi_{0s} + \Phi_{1s} \sum_{i=0}^{k-1} \Phi_{1s}^{-1} v_{s,t+i+1} \equiv \tilde{s}_{t+k}
\]

From this representation it is immediate that the state variables follow an aggregated VAR\(^k\)(1) with the following intercepts and slopes:

\[
\tilde{\Phi}_{0,s} = \Phi_{0,s} \cdot \sum_{i=0}^{k-1} \Phi_{1s} = \Phi_{0,s} \cdot \Theta(k) \quad \tilde{\Phi}_{1,s} = \Phi_{1,s}
\]

where we have defined a sequence of matrices parameterized by the aggregation horizon - \( k \), \( \Theta(k) = (I - \Phi_{1,s}) \cdot (I - \Phi_{1,s})^{-1} \).

The covariance matrix of the k-period shocks to the state variables is given by:

\[
Var_t \left[ \sum_{i=0}^{k-1} \Phi_{1s}^{-1} v_{s,t+i+1} \right] = \sum_{i=0}^{k-1} \left( \Phi_{1s}^{-1} \cdot \Sigma_{ss} \cdot (\Phi_{1s}^{-1})' \right) \equiv \tilde{\Sigma}_{ss}
\]

With these results we can re-express the k-period return as follows:

\[
\tilde{r}_{t+k} = k \cdot \Phi_{0,r} + \Phi_{1,r} \cdot \sum_{j=0}^{k-1} \Theta(j) \cdot \Phi_{0,s} + \Phi_{1,s} \cdot s_t + \sum_{j=0}^{k-1} v_{r,t+j+1} \\
+ \sum_{j=0}^{k-1} v_{r,t+j+1} \\
= k \cdot \Phi_{0,r} + \Phi_{1,r} \cdot \left( (kI - \Theta(k)) \cdot (I - \Phi_{1,s})^{-1} \cdot \Phi_{0,s} + \Theta(k) \cdot s_t + \sum_{j=0}^{k-1} \Phi_{1s}^{-1} v_{s,t+1+i} \right) + \\
+ \sum_{j=0}^{k-1} v_{r,t+j+1} 
\]

The form of the above expression confirms that the k-period returns also follow a first-order auto-regression with intercepts and slopes given by:

\[
\tilde{\Phi}_{0,r} = k \cdot \Phi_{0,r} + \Phi_{1,r} \cdot (kI - \Theta(k)) \cdot (I - \Phi_{1,s})^{-1} \cdot \Phi_{0,s} \\
\tilde{\Phi}_{1,r} = \Phi_{1,r} \cdot \Theta(k)
\]
The remaining two results that have to be established are the forms of the variance matrix of the k-period returns and the covariance matrix of k-period returns with the k-period ahead innovation to the state variables. We begin with the variance matrix of the k-period returns, \( \Sigma_{rr} \). From the expression for the k-period return we see that there are two components to the shock, related to the shocks to the state variables and returns, respectively. We compute their second moments sequentially.

\[
\text{Var}_t \left[ \Phi_{1,r} \cdot \sum_{j=0}^{k-1} \sum_{i=0}^{j-1} \Phi_{1,s}^{j-i} v_{s,t+i+j} \right] = \text{Var}_t \left[ \Phi_{1,r} \cdot \sum_{i=1}^{k-1} \left( \sum_{j=0}^{k-i-1} \Phi_{1,s}^j \right) v_{s,t+i} \right] \\
= \text{Var}_t \left[ \Phi_{1,r} \cdot \sum_{i=1}^{k-1} \left( (I - \Phi_{1,s}^{k-i}) \cdot (I - \Phi_{1,s})^{-1} \right) v_{s,t+i} \right] \\
= \sum_{i=1}^{k-1} \Phi_{1,r} \cdot \Theta(k-i) \cdot \Sigma_{ss} \cdot \Theta(k-i)' \cdot \Phi_{1,r}' \\
\text{Var}_t \left[ \sum_{j=0}^{k-1} v_{r,t+j} \right] = k \cdot \Sigma_{rr}
\]

The covariance term appearing in the variance of the k-period return is:

\[
\text{Cov}_t \left[ \Phi_{1,r} \cdot \sum_{j=0}^{k-1} \sum_{i=0}^{j-1} \Phi_{1,s}^{j-i} v_{s,t+i+j} \sum_{j=0}^{k-1} v_{r,t+j} \right] = \\
= \text{Cov}_t \left[ \Phi_{1,r} \cdot \sum_{i=1}^{k-1} \left( (I - \Phi_{1,s}^{k-i}) \cdot (I - \Phi_{1,s})^{-1} \right) v_{s,t+i} \sum_{j=1}^{k} v_{r,t+j} \right] \\
= \Phi_{1,r} \cdot \sum_{i=1}^{k-1} \Theta(k-i) \cdot \Sigma_{sr}
\]

Hence we arrive at the following formula for the variance of the k-period return:

\[
\text{Var}_t \left[ \sum_{i=0}^{k-1} r_{t+i} \right] = \sum_{i=1}^{k-1} \Phi_{1,r} \cdot \Theta(k-i) \cdot \Sigma_{ss} \cdot \Theta(k-i)' \cdot \Phi_{1,r}' + \\
k \cdot \Sigma_{rr} + 2 \Phi_{1,r} \cdot \sum_{i=1}^{k-1} \Theta(k-i) \cdot \Sigma_{sr} \equiv \tilde{\Sigma}_{rr} \tag{65}
\]

Lastly, we turn to the covariance of the k-period shocks to the state variables and the shocks to the k-period return:

\[
\text{Cov}_t \left[ \sum_{i=0}^{k-1} \Phi_{1,s}^{k-i} v_{s,t+i}, \Phi_{1,r} \cdot \sum_{j=0}^{k-1} \sum_{i=0}^{j-1} \Phi_{1,s}^{j-i} v_{s,t+i+j} + \sum_{j=0}^{k-1} v_{r,t+j} \right] \equiv \tilde{\Sigma}_{sr}
\]

Using the properties of the covariance operator, computing the sums and simplifying the notation using the \( \Theta(i) \) matrices allows us to re-express the covariance as:

\[
\tilde{\Sigma}_{sr} = \text{Cov}_t \left[ \sum_{i=1}^{k} \Phi_{1,s}^{k-i} v_{s,t+i}, \Phi_{1,r} \cdot \sum_{i=1}^{k} \left( (I - \Phi_{1,s}^{k-i}) \cdot (I - \Phi_{1,s})^{-1} \right) v_{s,t+i} + \sum_{j=1}^{k} v_{r,t+j} \right] \\
= \sum_{i=1}^{k-1} \Phi_{1,s}^{k-i} \cdot \Sigma_{ss} \cdot \Theta(k-i)' \cdot \Phi_{1,r}' + \sum_{j=1}^{k} \Phi_{1,s}^{k-j} \Sigma_{sr} \\
= \sum_{i=1}^{k-1} \Phi_{1,s}^{k-i} \cdot \Sigma_{ss} \cdot \Theta(k-i)' \cdot \Phi_{1,r}' + \Theta(k) \cdot \Sigma_{sr} \equiv \tilde{\Sigma}_{sr} \tag{66}
\]

48
Ultimately, we are in position to conclude that the aggregated $VAR^k(1)$ model takes the following form:

$$\begin{bmatrix}
\tilde{r}_{t+k} \\
\tilde{s}_{t+k}
\end{bmatrix} = \begin{bmatrix}
\tilde{\Phi}_{0,r} \\
\tilde{\Phi}_{0,s}
\end{bmatrix} + \begin{bmatrix}
0_{(1+n)\times(1+n)} & \tilde{\Phi}_{1,r} \\
0_{m\times(1+n)} & \tilde{\Phi}_{1,s}
\end{bmatrix} \cdot \begin{bmatrix}
0_{(1+n)\times 1} \\
s_t
\end{bmatrix} + \tilde{\nu}_{t+k}$$

where the covariance matrix of the shocks to the aggregated system is given by:

$$\tilde{\Sigma} = \begin{bmatrix}
\tilde{\Sigma}_{rr} & \tilde{\Sigma}_{rs} \\
\tilde{\Sigma}_{sr} & \tilde{\Sigma}_{ss}
\end{bmatrix}$$
Table 1: **Sources of time-series used in the construction of state variables and asset returns for the VAR(1) model.** The first panel provides the origin of the raw data used to estimate the model, while the second describes the variables included in the VAR(1) along with the acronyms used in tables reporting model estimates.

The return series for the value and growth indices are constructed as a value-weighted average of the returns on the six book-to-market/size sorted Fama-French portfolios. The weights are computed as the ratio of the market capitalizations of the underlying portfolios to the market capitalization of the respective index (defined in the caption to Figure 1). Hence the return on the value and growth indices at time $t$ is defined as follows:

$$r^V_t = r_t^{SMHI} \left( \frac{ME_t^{SMHI}}{ME_t^V} \right) + \frac{1}{2} r_t^{SMME} \left( \frac{ME_t^{SMME}}{ME_t^V} \right) + r_t^{BHHI} \left( \frac{ME_t^{BHHI}}{ME_t^V} \right) + \frac{1}{2} r_t^{BIME} \left( \frac{ME_t^{BIME}}{ME_t^V} \right)$$

$$r^G_t = r_t^{SMLO} \left( \frac{ME_t^{SMLO}}{ME_t^G} \right) + \frac{1}{2} r_t^{SMME} \left( \frac{ME_t^{SMME}}{ME_t^G} \right) + r_t^{BILO} \left( \frac{ME_t^{BILO}}{ME_t^G} \right) + \frac{1}{2} r_t^{BIME} \left( \frac{ME_t^{BIME}}{ME_t^G} \right)$$
Table 2: Summary statistics for variables used in VAR estimation. The dataset is comprised of monthly data from 1952:12 to 2003:12 (613 data points).

Table 3: Estimates of the equity-only VAR(1) system. The investable universe only includes the value (V) and growth (G) stock portfolios. The VAR estimates are obtained using monthly data from 1952:12 to 2003:12 (613 data points). The top panel contains the estimates of the VAR coefficients with t-statistics (round brackets) and bootstrap estimates of the 95%-confidence intervals (square brackets). The t-statistics are computed using Newey-West standard errors with 12 lags. The bootstrap estimates are produced from 10,000 paths (with length equal to the historical sample) simulated under the assumption that the estimated VAR process is the true data generating process. The rightmost column reports the regression $R^2$ and the p-value of the F-test for no predictability in parentheses. The bottom panel contains the residual correlation matrix for the VAR(1) shocks; entries on the diagonal correspond to monthly residual standard deviations.

Table 6: Welfare simulation results for the equity-only case by horizon, risk-aversion and rebalancing frequency. Panel A reports the certainty equivalents of wealth for the dynamic strategy with monthly rebalancing, which serves as the base case for the welfare loss computations. Panels B1-B4 report the welfare losses of dynamic strategies with lower rebalancing frequencies and the constant proportion strategy. The welfare loss ($\eta$) is computed as the percentage loss in the certainty equivalent of wealth between the proposed rebalancing scheme and the base case. Panels C1-C4 compute the maximal monthly management fee ($\phi$) an agent would be willing to pay in order to gain access to the dynamic monthly strategy. The fee is computed as $\phi = 1 - (1 + \eta)^{1/\gamma}$. The results are obtained by Monte Carlo simulation using 20,000 VAR paths sampled using the method of antithetic variates, with the same path set being used to evaluate the welfare loss in all cases. The certainty equivalent of wealth is computed by evaluating the mean utility realized across the simulated paths and computing, $W_{CE} = u^{-1}(E[u(W_T)])$. $\gamma$ denotes the investor’s coefficient of relative risk aversion.

Table 7: **Time-series variance of the portfolio allocation to value (V)**. The table presents a decomposition of the time-series variance of the portfolio allocation to value (V) in the equity-only case for an investor with relative risk aversion of \( \gamma \) who chooses her portfolio as if there perpetually were \( \tau \) periods remaining to the investment horizon. The table reports the total variance realized over the period 1952:12 to 2003:12 for which VAR data is available, and the fraction of the portfolio weight variance due to the intertemporal hedging component. Since the growth (G) portfolio weight for any horizon is defined as the residual between unity and the value portfolio weight, the analogous variances for the growth portfolio weight are identical.

Table 8: Welfare simulation results for the T-bills, bonds, and equities case by horizon, risk-aversion and rebalancing frequency. Panel A reports the certainty equivalents of wealth for the dynamic strategy with monthly rebalancing, which serves as the base case for the welfare loss computations. Panels B1-B4 report the welfare losses of dynamic strategies with lower rebalancing frequencies and the constant proportion strategy. The welfare loss (\(\eta\)) is computed as the percentage loss in the certainty equivalent of wealth between the proposed rebalancing scheme and the base case. Panels C1-C4 compute the maximal monthly management fee (\(\phi\)) an agent would be willing to pay in order to gain access to the dynamic monthly strategy. The fee is computed as \(\phi = 1 - (1 + \eta)^\frac{1}{T}\). The results are obtained by Monte Carlo simulation using 20,000 VAR paths sampled using the method of antithetic variates, with the same path set being used to evaluate the welfare loss in all cases. The certainty equivalent of wealth is computed by evaluating the mean utility realized across the simulated paths and computing, \(W_{CE} = u^{-1}(E[u(W_T)])\). \(\gamma\) denotes the investor’s coefficient of relative risk aversion.

</table>
Figure 1: Term-structure of the annualized log population arithmetic and geometric mean excess returns on the aggregate stock market (Mkt) and the 5-yr Treasury bond (B5).
Figure 2: Market capitalization of value and growth stock portfolios as a fraction of total market capitalization. The value (V) and growth (G) indices used in the VAR estimation are constructed using the data available on Prof. Ken French’s website. We use the time series of data available for six portfolios resulting from an intersection of two portfolios formed on size (market equity) and three portfolios formed on the ratio of book equity to market equity. The value index is defined to include the SMHI and BIHI portfolios, as well as, one half of the SMME and BIME portfolios. The growth index has the complementary composition and includes the SMLO and BILO portfolios, and one half of the SMME and BIME portfolios. To construct the time series of the market capitalizations of each of the indices we use the data on number of companies in each of the sub-portfolios ($N_t$) and their average market capitalization ($ME_t$). Thus the market capitalization of the value index index at time $t$ is defined as follows: $ME_t^V = N_t^{SMHI} ME_t^{SMHI} + \frac{1}{2} N_t^{SMME} ME_t^{SMME} + N_t^{BIHI} ME_t^{BIHI} + \frac{1}{2} N_t^{BIME} ME_t^{BIME}$. The market capitalization of the growth index (G) has the complementary definition.
Figure 3: Mean percentage optimal portfolio allocations in the equity-only case.
Figure 4: Mean percentage optimal allocations to cash, bonds, growth and value for investors with $\gamma = \{5, 10, 20\}$ (Panel A), and the optimal growth and value allocations re-scaled by the total equity allocation (Panel B).
Figure 5: Stock market allocation and active value tilt implied by the optimal equity portfolio. This figure decomposes the optimal allocation to value and growth stocks (Figure 4, Panel A) into an equivalent allocation to the market portfolio and an active value tilt. The allocations are computed for investors with \( \gamma = \{5, 10, 20\} \) who can invest in cash, bonds, and the growth and value portfolios.

Figure 6: Mean percentage allocations to cash, bonds, the aggregate stock market, and the optimal value tilt for investors with \( \gamma = 500 \).
