Co-Design of ANYtime Computation and Robust Control

Yash Vardhan Pant, Kartik Mohta, Houssam Abbas, Truong X. Nghiem, Joseph Devietti, Rahul Mangharam

Abstract—Control software of autonomous robots has stringent real-time requirements that must be met to achieve the control objectives. One source of variability in the performance of a control system is the execution time and accuracy of the state estimator that provides the controller with state information. This estimator is typically perception-based (e.g., Computer Vision-based) and is computationally expensive. When the computational resources of the hardware platform become overloaded, the estimation delay can compromise control performance and even stability. In this paper, we define a framework for co-designing anytime estimation and control algorithms, in a manner that accounts for implementation issues like delays and inaccuracies. We construct an anytime perception-based estimator from standard off-the-shelf Computer Vision algorithms, and show how to obtain a trade-off curve for its delay vs estimate error behavior. We use this anytime estimator in a controller that can use this trade-off curve at runtime to achieve its control objectives at a reduced energy cost. When the estimation delay is too large for correct operation, we provide an optimal manner in which the controller can use this curve to reduce estimation delay at the cost of higher inaccuracy, all the while guaranteeing basic objectives are met. We illustrate our approach on an autonomous hexrotor and demonstrate its advantage over a system that does not exploit co-design.

I. INTRODUCTION

Real-time control of physical systems, like autonomous robots, raises a number of timing and control-related issues at the interface between the controller that’s providing the actuation and the estimator that’s providing periodic state estimates to the controller. Some of these issues have to do with the inaccuracies introduced by the software implementation of both controller and estimator on a given hardware platform. Specifically, controllers are typically designed to accomplish the functional goals of the system under simplifying assumptions on the quality of the state estimate (e.g., no or fixed error), the estimation delay (e.g., no or fixed delay), and the actuation jitter (e.g., no jitter). Conversely, estimation algorithms are typically designed without regard to how their estimates will be used and under what operating conditions. In particular, an estimator will often run to completion; that is, its stopping criteria are designed to provide the best estimate, regardless of runtime or energy consumption. The problem addressed here is that as the real-time requirements on the closed-loop system become more stringent, this separation in the design and execution of controller and estimator can lead to degraded performance, as will be shown in Example 1. The goal of this paper is to present a rigorous framework for the joint design of the controller and estimator, in which the estimator explicitly presents a range of execution time/estimate error operating modes, and the controller switches between these modes in real-time to maintain control performance and reduce energy consumption.

Typical design practice determines the Worst-Case Execution Time (WCET) of the estimation task, and engineers the system to satisfy deadlines under WCET conditions. However, the actual execution time of such estimators is heavily dependent on the actual data being processed. So WCET considerations, whether computed online or offline, produce a conservative design. Moreover, classical timing analysis does not guarantee functional correctness of the closed-loop system. In addition, the best estimate is not always needed: sometimes a lower quality estimate, obtained with a smaller energy cost, is sufficient to achieve the control objectives. Finally, when obtaining better estimates requires longer runtimes of the estimation task, it may actually be detrimental to ask for the best estimate. For example, when the computational resources are overloaded, there may be a need to spend less time computing a state estimate.

Example 1: To illustrate the impact of estimation delay $\delta$ and estimate inaccuracy $\epsilon$ on control performance, we show a simple PID controlling the motion of a point mass in the $(x, y)$ plane. The position of the point mass must follow a reference constant trajectory, whose $x$ dimension is shown in Fig. 2 (the same plot can be obtained for the $y$ position). We simulate three cases of estimation (and therefore actuation) delay and error, where a larger delay value $\delta$ implies a smaller estimation error $\epsilon$. As can be noted in Fig. 2, the effect of delay can be non-negligible. Moreover, decreasing delay doesn’t necessarily imply better tracking performance: the effect of the concomitant estimation error...
must be taken into account. In this example, it can be seen that the increasing error causes the tracking performance to worsen. Running an estimation task with a fixed smaller delay but larger estimation error does not necessarily solve the problem of degraded performance, as can be seen in Fig. 2. Therefore, there is a need to rigorously quantify the trade-off between computation time and estimation error, then exploit that trade-off to achieve the best control performance under the problem constraints. Rather than always running the estimation task to completion, it is useful to have several estimation tasks with varying utilities (i.e., varying delay/error trade-offs). These can then be used at runtime to satisfy the control objectives.

In this work, we develop the above remarks into a co-design framework for a real-time control system, where the controller and estimator communicate via contracts. A contract is a guarantee requested by the controller, and fulfilled by the estimator, that the latter can provide an estimate with a certain maximum error \( \epsilon \), and within a certain deadline \( \delta \). Both the deadline and the error bound are part of the contract. Using these contracts, we show how the controller can throttle the execution time of the estimation task to preserve good performance and to reduce energy consumption. Our work focuses on estimators that incorporate computationally intensive Computer Vision (CV) algorithms, such as those used in autonomous robot navigation. We refer to these as perception-based estimators. Our experiments validate that the execution time of these algorithms is significant and far exceeds the computation time of the control software, and can have an effect on control performance.

Fig. 1 presents the proposed structure of contract-based estimation and control. It shows a traditional feedback loop incorporating estimator, controller and the physical system, augmented with the (Delay, Error) contract between controller and estimator. This contract forms the basis of the proposed approach.

**Summary of contributions.** We present a contract-based framework for the co-design of real-time controller and estimator algorithms, consisting of:

- a well-defined interface between control and estimation, in the form of operating modes or contracts on the accuracy and delay provided by the estimator (Section III),
- a controller design that can vary the accuracy and delay of the estimation to achieve control objectives at a lower energy cost (Sections IV, V), and
- a general procedure to compose run-to-completion estimation algorithms into a contract-based estimator (Section VI).

We illustrate our approach on an autonomous flying robot (shown in Fig. 13) and demonstrate performance and energy gains using our approach over a classical controller (Section VII).

**II. RELATED WORK**

Anytime algorithms [1] are a class of algorithms that can be interrupted at any point during their execution and still return a usable solution, usually with a monotonically improving quality with time. Contract algorithms [2] are one class of anytime algorithms where the interruption time is pre-determined for any given execution. Our approach, while similar to contract algorithms in the timing aspect, differs significantly as the meaning of a contract expands to including both time and quality of the solution (estimation error in our case).

Anytime algorithms have notably been studied for graph search [3], evaluation of belief networks [4] and GPU architectures [5].

As overloaded real-time systems are becoming increasingly common, anytime algorithms for control have become a topic of research interest. Most notably, Quevedo and Gupta [6], Bhattacharya and Balas [7], and Fontanelli et al. [8] have contributed to the topic. Our approach differs significantly from these works as the anytime computation assumption is on the perception-and-estimation algorithm and our controller is a robust controller which can switch between different operating modes of the anytime estimator. Also, while most of these works require either access to the full state of the system or have a fast estimator giving them the state estimate [7], our algorithm accounts for the computation time/error of the perception-and-estimation algorithms that are common in autonomous systems.

In real-time systems, recent work [9] uses Typical Worst Case Analysis of the software and Logical Execution Time
semantics to provide the controller with knowledge of the timing characteristics of the implementation. Our work, by contrast, profiles the estimation software directly to obtain timing and accuracy information. Whereas [9] is concerned with formal verification of a given controller, we design controllers to take advantage of delay/accuracy trade-offs in real-time. The effect of increasing computation time of a task on performance of a UAV has been explored in [10] by using a resource allocation algorithm similar to QRAM [11]. Our work differs from this as we consider the execution time of a task, the estimator, which is directly related to the control performance of a closed loop system and also formulate a control problem around it that provides mathematical guarantees on the performance of the closed loop system.

Also, in the field of computer architecture approximate computing approaches [12], [13], [14] have been studied, seeking time or energy savings by performing a computation approximately instead of precisely. While anytime algorithms and approximate computing share a high-level goal, approximate computing approaches are run-to-completion and also lack a feedback mechanism to permit computation and resources to be balanced dynamically. Additionally the time and energy scale that our approach works at is much higher than what approximate computing looks at.

III. CO-DESIGN OF ESTIMATION AND CONTROL

In a traditional control system, the controller is unaware of the implementation details of the estimation module and the estimation module is unaware of the requirements of the controller. For example, the design of a feedback controller might not take into account the fact that obtaining a state estimate from a video feed will take a non-negligible amount of time, which we refer to as the estimation delay. Conversely, the design of the perception and estimation module might not in general take into account the varying real-time constraints that the controlled system must satisfy. In order to improve performance of real-time closed loop systems using computationally and power limited platforms, we propose the co-design of estimation and control. The co-design involves using a contract-based framework for both estimator and controller. Namely, the controller requests the estimator to provide a state estimate within a certain deadline $\delta$ seconds and with a certain error bound $\epsilon$. We refer to the tuple $(\delta, \epsilon)$ as the contract between controller and estimator. The estimator then provides an estimate that respects the contract. By requesting estimates with varying contracts during system operation, the controller is able to adapt the closed-loop system performance in real-time according to the current condition of the physical system. For example, it can decide when an estimate is needed fast (but usually with higher error), and when a more accurate estimate is needed (but with greater delay). Note, the $(\delta, \epsilon)$ contract can also be thought of as setting an operating mode for the perception-and-estimation algorithm. A high-level view of this setup is shown in Fig. 1.

To ensure that the estimator can respect the contract (alternatively, that the controller is only requesting contracts that can be fulfilled by the estimator), the estimator is profiled off-line. Namely, the estimator’s parameters are varied and for each setting of the parameters, it is run on a profiling data set. This yields a finite set of $(\delta, \epsilon)$ values, each one corresponding to a setting of the parameters. These values can be plotted on a curve, which we call the error-delay curve made up of discrete points, $(\delta, \epsilon)$, represented by the set $\Delta$. Examples of such a curve are shown in Figs. 7 and 14. The detailed procedure for obtaining such a curve for a perception based algorithms is given in Section VI.

At run-time, when the estimator receives a $(\delta, \epsilon)$ contract request from the controller, it can adapt its execution paths to respect the contract, namely, to provide a state estimate in real-time within the requested error bound $\epsilon$, and within the requested deadline $\delta$.

In addition, the controller is designed with the knowledge
of the error-delay curve of the estimation algorithm, and requests contracts from that curve. Thus, the error-delay curve constitutes the interface between controller and estimator. This gives the controller the ability to leverage the flexible nature of the estimation algorithm to maximize some performance measure of control performance.

Fig. 4 shows the closed loop architecture in a system with co-design of the estimator and controller. In the co-designed system as presented in this paper, the controller can make the estimation algorithm switch to lower or higher time (and/or energy) consuming modes based on the control objective at the current time step. The main components of the co-design architecture are a contract based perception-and-estimation algorithm, a robust control algorithm that computes an input to be sent to the physical system being controller as well as the operating mode for the contract time estimator, and the interface between them. More details on these components are in the following sections.

A. Contract based perception algorithms

A contract based perception-and-estimation algorithm can operate at different deadlines and provide a usable solution for the control algorithm to operate on. This flexible operation is achieved by composing the algorithm of functional blocks that have different execution times and result in different qualities of outputs.

An example is a Computer Vision (CV) based Object recognition algorithm which is composed of different functional blocks of varying execution time which result in a different accuracy when linked together to provide the functionality of an object recognition algorithm. E.g. the pixel classifier in the first stage of such a CV algorithm could be a Gaussian Mixture Model with 2, 4, or 6 components, with more components providing better classification performance (over-fitting is ruled out by cross-validation) at the cost of more computation time. Functions with similar characteristics like example above, when profiled extensively offline and composed in the right order at run-time can be used to compose a contract time anytime perception and estimation algorithm. More details follow in section VI.

B. Interface between contract based perception and robust control

For the control algorithm to be able to leverage the flexible nature of the contract based perception algorithm, it must have information about the computation time versus output quality trade-off that the contract based perception algorithm offers. An interface that achieves this is obtained by representing the profiled behaviour of the contract based algorithm to varying deadlines, as points on a perception quality versus deadline (δ, ϵ) curve, e.g. in Fig. 7. With this profiled curve available to the controller at runtime, the exchange of information between the contract based perception-and-estimation algorithm and the control algorithm consists of the controller assigning a deadline (δ), or a contract to the perception algorithm while expecting a bound on the error (ϵ) of its output. The perception algorithm then returns an output after internally deciding the composition to best meet the deadline and the expected quality requirement. Through extensive offline profiling, we guarantee with a high degree of confidence that the contract based estimator does not violate the contract. This helps in formulating a control algorithm that provides mathematical guarantees on the feasibility of constraints for the safe operation and stability of the closed loop dynamic system as covered in section V.

C. Robust Control with contract based perception algorithm

The control algorithm is designed to pick the best operating point for the estimator, or the right (δ, ϵ) contract to request from the perception and estimation algorithm. This is done based on the current state of the physical system to maximize a performance measure while being robust to the varying computation time and the varying estimation errors of the estimator with different contracts as is provides estimates to the controller. In section V we present a control algorithm that achieves this while also guaranteeing feasibility of system constraints the stability of the closed loop system.

IV. ROBUST CONTROL WITH CONTRACT-BASED ESTIMATOR

In this section we present the mathematical formulation to model the controller and physical system from Fig. 1, and demonstrate how the controller can, in real-time, use knowledge of the estimator’s error-delay curve to decrease computation delay and power in an error-aware fashion.

A. System Model

Consider a hexrotor, which is an autonomous flying robot with six rotors, shown in Fig. 13. The state x of the hexrotor is made of its 3D position and 3D velocity. The input u to the robot consists of the desired pitch and roll angles, and the desired thrust. The hexrotor’s mission is to fly a pre-defined pattern given by $x_{ref}$, where $x_{ref}(t)$ gives the desired position at each time t. The dynamics of the hexrotor, relating the time-evolution of its state to the current state and input, can be linearized and approximated by the following Linear Time-Invariant (LTI) ODE:

$$\dot{x}(t) = A_x x(t) + B_x u(t) + w_c(t)$$

where $x \in \mathbb{R}^n$ is the state constrained to lie in a set $X \subseteq \mathbb{R}^n$, $u \in \mathbb{R}^m$ is the control input constrained to lie in a set $U \subseteq \mathbb{R}^m$, and $w_c \in \mathbb{R}^n$ is the bounded process noise assumed to lie in a set $\mathcal{W}_c \subseteq \mathbb{R}^n$. $A_x \in \mathbb{R}^{n \times n}$ and $B_x \in \mathbb{R}^{n \times m}$ are matrices. LTIs model a wide range of systems, and our results apply to arbitrary LTIs of the form given in (1) with compact and convex constraint sets $X$, $U$, and $\mathcal{W}_c$. The sets $X$ and $U$ are part of the problem statement and are either chosen by the designer or determined by physical constraints.

For the hexrotor, $X$ captures limits on the state such that the LTI dynamics provide a good approximation of the true nonlinear dynamics. The set $U$ restricts the inputs to values that can be supported by the rotors.
B. Time-Triggered Sensing and Actuation

For flight the hexrotor needs to determine its current position and speed, i.e., it needs to produce an estimate of its current state \( x \). It does so by taking a video during flight through a downward facing camera, detecting and tracking features across frames, and deducing its own position relative to these features. The camera captures a new frame every \( T > 0 \) seconds, thus resulting in periodic measurements at instants \( t_{s,k} = kT; \) where \( k \in \mathbb{N} \).

The sampled measurement is fed to the estimator that computes the state estimate \( \hat{x}_k := \hat{x}(t_{s,k}) \) with the desired accuracy \( \epsilon_k \) determined by the controller in the previous time step. The controller then uses this state estimate to compute the control input \( u_k \) as well as decide on the state estimate’s delay and accuracy contract \((\delta_k, \epsilon_k)\) for the next step. This control is applied to the physical system according to (1) at instant \( t_{a,k} = t_{s,k} + \delta_k + \tau_k \), where \( \tau_k \) is the time it takes to compute the input. See Fig. 5.

In our setting, the controller has access to the delay-error curve \( \Delta \) of the estimator, and makes contract selections from that curve. This curve is obtained offline as explained in Section III, and exemplified in Section VI. We remark that in each step \( k \geq 0 \), the estimation accuracy \( \epsilon_k \) and hence the delay \( \delta_k \) are already decided in the previous step and known to the controller. In the first step \( k = 0 \), the initial accuracy \( \epsilon_0 \), the initial delay \( \delta_0 \), and the initial control input \( u_{-1} \) are chosen by the designer.

C. Control Performance

The goal of the controller is twofold: it needs to ensure that the reference pattern is adhered to as closely as possible, and that the energy consumed to fly this pattern is minimized. Thus we may define two (stage) cost functions: first, \( \ell(x, u) = (x - x_{ref})^T Q(x - x_{ref}) + u^T R u \) defines a weighted sum of the tracking error (first summand) and the input power (second summand). Here, \( Q \) and \( R \) are positive semidefinite matrices. Second, \( \pi(\delta) \) captures the average power consumed to perform an estimation of duration \( \delta \). This power information is collected offline during the estimator profiling phase. The paper’s formulation holds for much more general stage cost functions. These stage cost functions are chosen by the designer to achieve a desired control performance.

The total cost function that the controller minimizes is then \( J = \sum_{k=0}^{M} \ell(x_k, u_k) + \alpha \pi(\delta_k) \), where \( M \geq 0 \) is the duration of the system’s operation.

D. Discretized Dynamics

Because of time-triggered sensing and actuation, from time \( t_{a,k} \) to \( t_{a,k} \), the previous control input \( u_{k-1} \) is still used. Then at \( t_{a,k} \) the new control input \( u_k \) is computed and applied by the controller (see Fig. 5). For simplification, we assume the computation time for the controller \( (\tau) \) to be constant and lump it with the time for the estimator \( (\delta) \). This is justified experimentally for our problem (in Sec.VII-B) where the time for the controller is negligible compared to the time taken by the estimation algorithm. The discretized dynamics are given by

\[
x_{k+1} = Ax_k + B_1(\delta_k)u_{k-1} + B_2(\delta_k)u_k + w_k, \quad k \geq 0
\]

in which

\[
A = e^{A \tau}, \quad w_k = \int_0^\tau e^{A(T-t)}w_c(t_{s,k} + t)dt
\]

\[
B_1(\delta) = \int_0^\delta e^{A(T-t)}B_{1c}dt, \quad B_2(\delta) = \int_0^\delta e^{A(T-t)}B_{2c}dt.
\]

Here \( w_c \) is the accumulated process noise during the interval, and is constrained to lie in a compact convex set \( W \) because \( w_c(t) \) lies in the convex compact set \( W_c \) and \( T \) is finite. Note that both the current control \( u_k \) and the previous control \( u_{k-1} \) appear in (2). Furthermore, the input matrices \( B_1(\delta_k) \) and \( B_2(\delta_k) \) depend on the delay \( \delta_k \). The estimation accuracy \( \epsilon_k \) affects the state estimate \( \hat{x}_k \) used by the controller to compute \( u_k; \) therefore \( \epsilon \) indirectly affects the dynamics via the control input.

V. ROBUST MODEL PREDICTIVE CONTROL SOLUTION

In this section we give an overview of the Robust Adaptive Model Predictive Controller (RAMPC) that we use in the contract-based setup of Fig. 4. The mathematical details and derivations are available in the online technical report [15]. Experiments confirm that the following controller can be run in real-time, and its computation uses a negligible amount of time relative to the estimation delay.

A. Solution overview

Recall the operation of the contract-based control and estimation framework as presented in Section III and Fig. 4. First, the estimator is profiled offline to obtain its delay-error curve, which we denote by \( \Delta \). The curve \( \Delta \) represents a finite number of \((\delta, \epsilon)\) contracts that the estimator can satisfy. At every time step \( k \), the controller receives a state estimate \( \hat{x}_k \) and uses it to compute two things: first is the control input \( u_k \) to be applied to the physical system at time \( t_{a,k} \). The second is the contract \( (\delta_{k+1}, \epsilon_{k+1}) \in \Delta \) that will be requested from the estimator at the next step. At \( k + 1 \), the estimator provides an estimate with error at most \( \epsilon_{k+1} \) and within delay \( \delta_{k+1} \). Finally, recall that \( J = \sum_{k=0}^{M} (\ell(x_k, u_k) + \alpha \pi(\delta_k)) \) combines tracking error and input power in the \( \ell \) terms, and estimation power consumption in the \( \pi \) terms. The scalar \( \alpha \) quantifies the importance of power consumption to the overall performance of the system.

The contract-based controller’s task is to find a sequence of inputs \( u_k \in U \) and of contracts \( (\delta_k, \epsilon_k) \in \Delta \) such that the cost \( J \) is minimized, and the state \( x_k \) is always in the
set $X$. The challenge in finding the control inputs is that the controller does not have access to the state $x_k$, but only to an estimate $\hat{x}_k$. The norm of the error $e_k = x_k - \hat{x}_k$ is bounded by the contractual $\epsilon_k$, which varies at each time step.

Fix the **prediction horizon** $N \geq 1$. Assume that the current contract (under which the current estimate $\hat{x}_k$ was obtained) is $(\delta_k, \epsilon_k)$, and that the previously applied input is $u_{k-1}$. To compute the new input value $u_k$ and next contract $(\delta_{k+1}, \epsilon_{k+1})$, the proposed **Robust Adaptive Model Predictive Control (RAMPC)** seeks to solve the following optimization problem which we denote by $\mathbb{P}_\Delta(x_k, \delta_k, \epsilon_k, u_{k-1})$:

$$J^*_{\delta, \epsilon}[0 : N] = \min_{u_k} \sum_{j=0}^{N} (\ell(x_{k+j}, u_{k+j}) + \alpha \pi(\delta_k))$$  \hspace{1cm} (3)

Here, RAMPC needs to find the optimal length-$N$ input sequence $u^* = (u^*_k, \ldots, u^*_{k+N}) \in U^N$, corresponding state sequence $x = (x_k, \ldots, x_{k+N}) \in X^N$, delay sequence $\delta = (\delta_k, \ldots, \delta_{k+N})$ and error sequence $\epsilon = (\epsilon_k, \ldots, \epsilon_{k+N})$ such that $(\delta_k, \epsilon_k) \in \Delta$, which minimize the $N$-step cost $J^*[0 : N]$. In the remainder of this section we discuss how to make this problem tractable. As in regular MPC [16], once a solution $u^*$ is found, only the first input value $u^*_k$ is applied to the physical system, thus yielding the next state $x_{k+1}$ as per (2). At the next time step $k + 1$, RAMPC sets up the new optimization $\mathbb{P}_\Delta(x_{k+1}, \delta_{k+1}, \epsilon_{k+1}, u_{k+1})$ and solves it again.

To make this problem tractable, we first assume that the mode is fixed throughout the $N$-step horizon, i.e. $(\delta_{k+j}, \epsilon_{k+j}) = (\delta, \epsilon)$ for all $1 \leq j \leq N$. Thus for every value $(\delta, \epsilon)$ in $\Delta$, we can setup a different problem (3) and solve it. Let $J^*_{\delta, \epsilon}$ be the corresponding optimum. The solution with the smallest objective function value yields the input value $u^*_k$ to be applied and the next contract $(\delta^*, \epsilon^*)$.

Because RAMPC only has access to the state estimate, we extend the RMPC approach in [17], [18]. Namely, the problem is solved for the **nominal dynamics** which assume zero process and observation noise ($w_k = 0$) and zero estimation error ($e_k = x_k - \hat{x}_k$) over the prediction horizon. Let $\bar{x}$ be the state of the system under nominal conditions. To compensate for the use of nominal dynamics, RMPC replaces the constraint $\{x_{k+j}, u_{k+1+j}\} \in X \times U := Z$ by $\{\bar{x}_{k+j}, u_{k+1+j}\} \in \tilde{Z}_j(\epsilon, \epsilon)$, where $\tilde{Z}_j(\epsilon, \epsilon) \subset \tilde{Z}$ is ‘shrunk’ by an amount corresponding to $\epsilon$, as explained in the technical report [15]. Intuitively, by forcing $(\bar{x}_{k+j}, u_{k+1+j})$ to lie in the reduced set $\tilde{Z}_j(\epsilon, \epsilon)$, the bounded estimation error and process noise are guaranteed not to cause the true state and input to exit the constraint sets $X$ and $U$.

The tractable optimization for a given $(\delta, \epsilon)$, denoted by $\mathbb{P}_{\delta, \epsilon}(\bar{x}_k, \delta_k, \epsilon_k, u_{k-1})$, is then

$$J^*_{\delta, \epsilon} = \min_{u_k} \sum_{j=0}^{N} (\ell(\bar{x}_{k+j}, u_{k+j}) + \alpha \pi(\delta_k))$$  \hspace{1cm} (4) \hspace{1cm} \text{s.t. } \forall j \in \{0, \ldots, N\}

\begin{align*}
\bar{x}_{k+1} &= A\bar{x}_k + B_1(\delta_k)u_{k+1} + B_2(\delta_k)u_{k+1} \\
(\bar{x}_{k+j}, u_{k+1+j}) &\in \tilde{Z}_j(\epsilon_k, \epsilon)
\end{align*}

**Algorithm 1** Robust Adaptive MPC algorithm with Anytime Estimation.

1: $(\delta_0, \epsilon_0)$ and $u_{-1}$ specified by designer
2: Apply $u_{-1}$
3: for $k = 0, 1, \ldots, M$ do
4: Estimate $\hat{x}_k$ with guarantee $(\delta_k, \epsilon_k)$
5: for each $(\delta, \epsilon) \in \Delta$ do
6: $J^*_{\delta, \epsilon}$ Solve $\mathbb{P}_{\delta, \epsilon}(\hat{x}_k, \delta_k, \epsilon_k, u_{k-1})$
7: end for
8: $(\delta^*, \epsilon^*) \leftarrow \text{argmin}_{(\delta, \epsilon)} J^*_{\delta, \epsilon}$
9: Apply control input $u_k = u^*_k$ and estimation mode $(\delta_{k+1}, \epsilon_{k+1}) = (\delta^*, \epsilon^*)$
10: end for

We prove the following result in the technical report [15]:

**Theorem 5.1:** If at the initial time step there exists a contract value $(\delta, \epsilon) \in \Delta$, an initial state estimate $\hat{x}_0 \in X$, and an input value $u_{-1} \in U$, such that $\mathbb{P}_{\delta, \epsilon}(\hat{x}_0, \delta_0, \epsilon_0, u_{-1})$ is feasible then the system (2) controlled by Alg. 1 and subjected to disturbances constrained by $u_k \in \mathcal{W}$ robustly satisfies the state constraint $x \in X$ and the control input constraint $u \in U$, and all subsequent iterations of the algorithm are feasible.

**VI. CONTRACT BASED PERCEPTION ALGORITHMS**

In Section III, we postulated the existence of an Estimation Error vs Computation Delay curve $\Delta$. This curve is used at every time step by the controller to determine the operating point $(\delta, \epsilon)$ for the next time step. In this section we demonstrate in detail how such a curve may be obtained for particular applications and how points along the curve are realized at runtime by the contract based perception algorithms.

**A. Profiling And Creating an Anytime Contract Based Perception-and-Estimation Algorithm**

The first step towards profiling a contract-based estimator is to identify the individual components (or algorithms) of the perception tool chain. The second step is to identify parameters of each component, such that modifying the values of these parameters leads to a change in the execution time and accuracy of the component’s output. This may be as simple as changing the number of iterations in a loop [12] or finding alternate implementations with different resultant execution times $\delta$ and estimation error $\epsilon$. We call these parameters *knobs* of the component. We implement this procedure on a Computer Vision (CV)-based object recognition tool chain. An overview of the tool chain is shown in Fig. 6.

The CV tool chain takes in a video stream and tracks an Object Of Interest (OOI) across the frames. The first stage of the chain is a pixel classifier that assigns to each pixel of the image (after potential pre-processing) the probability of its being a pixel of interest, i.e., of belonging to an OOI or being a part of the background. A binary image is then
obtained which assigns the value 1 to pixels of interest, and 0 to all others. Next, filtering and a Connected Components (CC) algorithm is run on the binary image to get rid of noise in the classification process and segment its 1-valued pixels into disconnected objects. A shape classifier is then run on each object to determine whether it is of interest or not.

In our implementation, the pixel classifier is a Gaussian Mixture Model (GMM) classifier, whose knob is the number of components in the GMM. Fewer Gaussians in the GMM yield a faster but less accurate classifier while more Gaussians will result in a higher execution time but provide better classification performance. Knob values that cause data overfit are discarded by a cross-validation stage as is standard.

The filtering and Connected Components algorithm are lumped into one stage and have a two-valued knob to choose between a 4-connected and 8-connected component implementation. The shape classifier is also a GMM, but the knob for it is the number of shape features (like eccentricity and lengths of major and minor axes). In our experiments the number of knob settings for the entire chain is \( K = (\#\text{Gaussians for pixel classifier}, \#\text{neighbors for CC}, \#\text{features for shape classifier}) \), and has a total of \( 3 \times 2 \times 2 = 12 \) values.

Note that for any given component in the chain, the relation between knob value and quality of output is not necessarily monotonic. The pixel and shape classifiers are machine learning algorithms that need to be trained on a training set before being used and like all machine learning algorithms, their output quality for a given knob setting will depend on the actual data set. The same is a fortiori true of the quality of the output of the entire chain. This is also reflected in Fig. 7 which shows the mean perception error\(^1\) and the 90\(^{th}\) percentile execution time for the different knob settings.

The final step is to profile all the possible combinations of knobs by running the tool chain on a test data set. This profiling gives us: a) the output quality (or accuracy) of the perception-and-estimation tool chain under consideration, and b) information about execution times for the stages of the perception tool chain under different knob settings. This information gathered offline is useful for making decisions at run-time. Fig. 7 shows the profiled performance of the CV tool chain.

B. Run-time execution of the contract-based perception algorithm

Having profiled the components of the contract-based perception algorithm, we can make run-time decisions for knob settings in order to realize a given \((\delta, \epsilon)\) contract.

This is the equivalent of selecting different versions of tasks (knobs for stages) and scheduling them in sequential order to best perform the object recognition task while meeting the given time contract or deadline. Fig. 6 shows the different task versions for each knob in the different stages and the resulting schedule based on the knob settings for the stages. The offline profiling allows us to set the knobs such that we can achieve a feasible schedule for the given deadline, \( \delta \) while maximizing the utility, or the expected accuracy of the perception algorithm.

C. Visual Odometry

Another algorithm we consider and later use in Section VII is the Semi-Direct Monocular Visual Odometry (SVO) [19]. The visual odometry algorithm detects corners in an image and tracks them across video frames to perform self-localization of a moving robot. These estimates are used in the closed loop control system that flies the hexrotor, hence it is important for the visual odometry to run at or faster than frame rate in order to provide a timely state estimate to the control algorithm. The number \#C and quality of corners detected in a frame directly affects the runtime of the tool chain.

\(^{1}\)Error is the distance between the true centroid and the estimated centroid of the OOI.
corner detector and the resulting quality of the state estimate. Generally speaking, detecting more corners requires a longer runtime, and results in better self-localization as long as we are analysing a feature rich scene, i.e., assuming acceptable quality of the detected corners. Thus the number \#C of corners is a knob which can be varied to obtain an error-delay curve for self-localization with the visual odometry algorithm. If the scene is not rich enough in features, and a sizeable fraction of the \#C corners are of poor quality (i.e., unstable or hard to track across frames), then we can expect the self-localization error to actually increase as the poor quality of the unstable corners detected adds noise to the visual odometry estimates.

Fig. 14 shows the error-delay curve of self-localization error using the SVO. The curve was obtained on an Odroid-U3 [20], which is the same processor as the one used on the hexrotor for on-board computation. For each value of the knob \#C (i.e., each requested number of corners), we ran the visual odometry algorithm on a video sequence recorded by the downward facing camera on the hexrotor while flying certain pre-set patterns. Ground truth for computing the self-localization error was obtained using a Vicon motion capture system which provides position estimates with better than millimeter level precision. As we repeat each flight several times, this results in a distribution of (δ, ϵ) values for each value of \#C. We retained the 90th percentile values for δ and ϵ, since these can be used as the worst-case estimates and delays by the controller of Section IV. It can be seen that a larger number of requested corners produces a smaller estimation error and longer runtime. Starting at 250 corners, the error increases, however. We hypothesize this is due to the decreasing quality of the corners being returned by the corner detection algorithm.

VII. CASE STUDY: REAL-TIME FEEDBACK CONTROL OF A HEXROTOR WITH CONTRACT BASED ESTIMATION AND ROBUST CONTROL

A. Experimental setup

To evaluate our methodology on a real platform, we applied it to a hexrotor tasked with repeatedly following a given circular trajectory. We use SVO (Section VI) as estimator and RAMPC as the controller. The obtained execution time distributions for SVO are shown in Fig.15. Details of the experimental setup are in the online technical report [15].

B. Experimental Evaluation

After profiling the performance of the perception and estimation algorithm and formulating the Robust Adaptive MPC controller for the hexrotor linearized around hover and modelled as an LTI system (Eq. 1), we experimentally evaluate the tracking performance and estimated energy consumption based on actual flights around a pre-defined trajectory. For comparison, we use a Model Predictive Controller with the same cost function and initial feasible sets as in our Robust MPC formulation. The MPC controller is an appropriate baseline against which to measure the benefits of our co-design method, as it is a similar control algorithm that does not leverage co-design and is unaware of the estimator algorithm that gives it a state estimate.

For the evaluation, we fly in a predefined circular trajectory, repeating the experiment 10 times to gather enough data to conclusively measure the performance of RAMPC for different values of α and MPC with fixed modes of (δ, ϵ). Note that since the controller was a sampled discrete-time controller working with simulated 20Hz camera updates, this realistically restricts us to using modes of estimator operation with delay δ less than 1/20s, i.e. modes corresponding to 50, 100, 150 and 200 maximum corners (see Fig. 14). These modes and their estimated power consumption is in Table I. Note, \#C represents the maximum number of corners requested, ϵ shows the worst case error bound on the state estimate, δ is the 90th percentile execution time for that mode, and P represents the expected power consumption in that mode as profiled offline. Note, the computation time for both the RAMPC and the MPC was less than 1ms.
so we neglect it in comparison to the time for estimation. This power consumption is the computation power used by a particular mode in excess to the idle power for the Odroid used for profiling, which was 1.5W.

\begin{table}[h]
\centering
\caption{Estimation modes used in the experiment.}
\begin{tabular}{|c|c|c|c|c|}
\hline
Mode & RC & $\epsilon$ & $\delta$ (ms) & $P$ (W) \\
\hline
0 & 50 & 43.88 & 0.028 & 0.778 \\
1 & 100 & 29.82 & 0.0237 & 0.862 \\
2 & 150 & 34.66 & 0.0230 & 0.870 \\
3 & 200 & 38.01 & 0.0113 & 0.951 \\
\hline
\end{tabular}
\end{table}

C. Experimental Results

Once the flights are complete, to get a more accurate picture of how the controllers really performed, we use the following function to measure tracking performance at each time step.

$$J_{true}(t) = (x(t) - x_{ref}(t))^T Q(x(t) - x_{ref}(t)) + u(t)^T R u(t)$$

Note that since we have access to the true position and velocities ($\dot{x}(t)$) of the hexrotor with the Vicon system, we can obtain the true tracking cost. Table II shows the mean of the above function over the 10 flights for both MPC across all fixed modes and RAMPC with different values of $\alpha$. It also shows the estimated energy consumption based on the time spent in each mode (which can be seen in Table III for RAMPC). RAMPC shows better tracking performance (lower mean $J_{true}$) than MPC in all cases, except for $\alpha = 0.2$, thus demonstrating the improved control performance that can be obtained by dynamically switching between estimation modes in-flight at runtime.

Fig. 10 shows how the tracking cost ($J_{true}$) evolves over time for RAMPC (with $\alpha = 0$) and MPC (fixed mode 0) for a portion of the hexrotor flight. The estimator modes selected by RAMPC are overlaid in orange.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{tracking_cost_vs_energy.png}
\caption{Tracking cost at each time step for MPC (fixed mode 0 estimator) and RAMPC with $\alpha = 0$. Note how the RAMPC performs better (lower cost) than the MPC and there is dynamic switching of estimator modes at runtime leading to improved performance for the RAMPC.}
\end{figure}

\begin{table}[h]
\centering
\caption{Tracking performance and computation energy}
\begin{tabular}{|c|c|c|c|c|}
\hline
Controller & Est. Mode & $\alpha$ & $E_{J_{true}}$ & $\sigma_J$ (J) & Energy (J) \\
\hline
MPC & 0/ - & 1.0903 & 0.104 & 43.89 \\
MPC & 1/ - & 1.0760 & 0.098 & 49.60 \\
MPC & 2/ - & 1.0762 & 0.088 & 54.15 \\
RAMPC & /0 & 0.8856 & 0.079 & 49.28 \\
RAMPC & /0.001 & 1.0029 & 0.093 & 48.90 \\
RAMPC & /0.01 & 1.0280 & 0.089 & 48.69 \\
RAMPC & /0.05 & 1.0502 & 0.096 & 46.33 \\
RAMPC & /0.1 & 1.0801 & 0.086 & 46.01 \\
RAMPC & /0.2 & 1.0776 & 0.083 & 44.49 \\
\hline
\end{tabular}
\end{table}

Fig. 11 shows that RAMPC provides better tracking performance while using less energy to do so. For any fixed energy budget (a point on the x-axis), RAMPC delivers lower tracking cost (y-axis) than MPC. While MPC’s tracking error is relatively constant across modes, RAMPC is able to balance tracking error with energy consumption by varying the $\alpha$ parameter. RAMPC’s switching between estimation modes improves not only the control performance but also energy efficiency.
the low-power (but less accurate) mode 0 as $\alpha$ increases.

**VIII. Conclusion**

In this paper we presented a contract-based methodology for co-design of estimation and control for autonomous systems. The basic idea is that the control algorithm requests a delay and estimation error $(\delta, \epsilon)$ contract that the perception- and-estimation algorithm realizes. The control algorithm we designed aims to set time-varying contracts to maximize a performance function while respecting feasibility constraints and stability under the time varying execution delay and estimation error from the estimator. We also illustrate how the contract-based perception-and-estimation algorithm is designed offline and used at run-time to best meet the $(\delta, \epsilon)$ contracts set for it. Through a case study on a flying hexrotor, we showed the applicability of our scheme to real-time closed loop system. The experimental results show the good performance of our scheme and how it outperforms regular Model Predictive Control which does not leverage co-design. A key result showed how our closed loop solution is more energy efficient than MPC while achieving better tracking performance. A focus of ongoing research is to overcome the necessity of the contracts always being met by the estimator. Another focus is on an automated tool chain to profile perception algorithms commonly used in autonomous systems.
