Chemical and mechanical nerve root insults induce differential behavioral sensitivity and glial activation that are enhanced in combination

Abstract

Both chemical irritation and mechanical compression affect radicular pain from disc herniation. However, relative effects of these insults on pain symptoms are unclear. This study investigated chemical and mechanical contributions for painful cervical nerve root injury. Accordingly, the C7 nerve root separately underwent chronic gut exposure, 10gf compression, or their combination. Mechanical allodynia was assessed, and glial reactivity in the C7 spinal cord tissue was assayed at days 1 and 7 by immunohistochemistry using GFAP and OX-42 as markers of astrocytes and microglia, respectively. Both chronic gut irritation and 10gf compression produced ipsilateral increases in allodynia over sham ($p < 0.048$); combining the two insults significantly ($p < 0.027$) increased ipsilateral allodynia compared to either insult alone. Behavioral hypersensitivity was also produced in the contralateral forepaw for all injuries, but only the combined insult was significantly increased over sham ($p < 0.031$). Astrocytic activation was significantly increased over normal ($p < 0.001$) in the ipsilateral dorsal horn at 1 day after either compression or the combined injury. By day 7, GFAP-reactivity was further increased for the combined injury compared to day 1 ($p < 0.001$). In contrast, spinal OX-42 staining was generally variable, with only mild activation at day 1. By day 7 after the combined injury, there were significant ($p < 0.003$) bilateral increases in OX-42 staining over normal. Spinal astrocytic and microglial reactivity follow different patterns after chemical root irritation, compression, and a combined insult. The combination of transient compression and chemical irritation produces sustained bilateral hypersensitivity, sustained ipsilateral spinal astrocytic activation and late onset bilateral spinal microglial activation.

1. Introduction

Nearly one-third of Americans suffer from acute, chronic, or chronic intermittent pain; chronic pain affects as many as 1/2

of the general population (Hasselstrom et al., 2002; Elliott et al., 1999). In particular, disc herniation with nerve root compression is the most common cause of radicular pain (Frymoyer, 1988; Hart et al., 1995; Ohnmeiss et al., 1997; Atlas et al., 2005).

Low back pain and sciatica often result from disc herniation (Boos et al., 1995); cervical disc herniation, while not as common as lumbar disc herniation, is nonetheless a leading cause of cervical radiculopathy (Ellenberg et al., 1994). Both chemical and mechanical factors contribute to radicular pain from disc herniation; the inflammatory material of the disc comes in contact with the nerve root, causing impingement and compression (Wall and Melzak, 1994; Rydevik et al., 1996; Olmarker and Myers, 1998). Disc tissue, particularly the nucleus pulposus, initiates an inflammatory response and produces and releases pro-inflammatory cytokines (Weiler et al., 2004; Saal, 1995; Goupille et al., 1998; Murata et al., 2004; Mulleman et al., 2005; Yoshida et al., 2005). For these reasons, the common approach to clinical treatment for painful disc herniation is surgery to remove the inflammatory material and unload the root (Loupasis et al., 1999; DeLeo and Winkelstein, 2002).

Despite the common notion that removing a putative insult can alleviate pain, there remains uncertainty about whether mechanical or chemical factors contribute more to pain from a disc herniation. In fact, surgery to relieve pressure to nerve roots does not always provide pain relief (Loupasis et al., 1999; Mulleman et al., 2005). These surgical studies imply that either chronic radicular pain is mediated by a chemical component that is not detectable through conventional imaging, or that a transient compressive insult may induce persistent pain. Chemical mediators, transient compression, or their combination may have a mechanistic role in cervical nerve root pain.

Many pain models have been developed to mimic clinical lumbar disc herniation (McCarron et al., 1987; Olmarker and Myers, 1998; Hou et al., 2003; Murata et al., 2004, 2005). Either nucleus pulposus is expelled by a small injection of air, or excised and applied directly to the nerve root (Olmarker et al., 1993, 1995, 1997, 2002; Otani et al., 1997; Olmarker and Myers, 1998; Yabuki et al., 1998; Skouen et al., 1999; Kawakami et al., 2003; Cornefjord et al., 2004; Kallakuri et al., 2005; Onda et al., 2005). These models induce behavioral hypersensitivity, as measured by allodynia, (pain provoked by a normally non-painful stimulus) and hyperalgesia (an increased response to a painful stimulus). While autologous disc material may be a clinically relevant model of the local injury scenario, such approaches present logistical challenges and do not enable separation of the specific and relative effects of either the mechanical and/or chemical contributions of the insult. As such, lumbar radiculopathy models have also separated these injury components to investigate their effects on behavioral hypersensitivity (Olmarker et al., 1993; Maves et al., 1993; Kawakami et al., 1994a,b; Kajander et al., 1996; Colburn et al., 1999; Hashizume et al., 2000; Hou et al., 2003; Murata et al., 2004; Winkelstein and DeLeo, 2004; Hubbard and Winkelstein, 2005). Though radicular pain models implement ligation with chromic gut to simultaneously apply compression and chemical irritation in low back pain (Maves et al., 1993; Kawakami et al., 1994a,b; Kajander et al., 1996; Xu et al., 1996; Colburn et al., 1999; Hashizume et al., 2000; Winkelstein and DeLeo, 2004; Robinson and Meert, 2005), mechanistic information for cervical disc herniation is limited.

Spinal glia contribute to the onset and development of neuropathic and radiculopathic pain (Colburn et al., 1999; Hashizume et al., 2000; Winkelstein and DeLeo, 2002; Newman, 2003; Watkins and Maier, 2003; McMahon et al., 2005; DeLeo et al., 2006; Narita et al., 2006). Activation of spinal microglia,

the resident macrophages of the central nervous system, occurs before astrocytic activation, and includes their transformation to a phagocytic state, increases in cell surface markers, and release of inflammatory mediators (Watkins and Maier, 2003; McMahon et al., 2005; DeLeo et al., 2006). Ligation with chromic gut suture elicits greater spinal microglial activation than silk suture, despite similar astrocytic activation for the two suture types (Hashizume et al., 2000). It remains to be seen whether spinal glial activation is produced following cervical nerve root chemical irritation alone, and if so, whether it is modulated with the addition of transient compression.

While many studies have utilized chromic gut suture to mimic disc herniation, no report to date has separated mechanically and chemically induced behavioral sensitivity; nor have these effects been studied for a transient compression. This study examined the hypothesis that exposure of the cervical nerve root to either a chemical stimulus (chromic gut suture material) or transient mechanical compression of the nerve root produces behavioral hypersensitivity and spinal glial activation that are increased when the two insults are combined. This hypothesis was tested by applying either transient compression or chromic gut directly to the cervical nerve root, or both insults simultaneously. Rats underwent separate procedures: cervical nerve root exposure to chromic gut suture material (*chromic exposure*), 10gf transient compression (*10gf compression*), chromic gut exposure with supplemental compression (*chromic+10gf compression*), or root exposure (*sham*). Mechanical allodynia was measured in bilateral forepaws and cervical spinal cord tissue was harvested on days 1 and 7 for immunohistochemical analysis to detect astrocytic and microglial reactivity in the bilateral dorsal horns at C7. Both qualitative and quantitative methods were used to assess glial activation in order to compare the findings to the literature (Colburn et al., 1999; Hubbard and Winkelstein, 2005) and to provide objective quantification of activation. The goal of this study was to identify the relative roles of chemical irritation and transient mechanics in mediating behavioral sensitivity from cervical nerve root injury and to provide insight into relationships between spinal glial activation and behavioral outcomes.

2. Results

2.1. Behavioral hypersensitivity

Ipsilateral mechanical allodynia was present following all types of insults: *chromic exposure*, *10gf compression* and *chromic+10gf compression*. Sham procedures did not produce increases in allodynia over baseline in either forepaw (Figs. 1 and 2). Exposure of the nerve root to chromic gut material produced an immediate, albeit slight, increase in mechanical allodynia in the ipsilateral forepaw (Fig. 1). This increase was significant over *sham* ($p < 0.041$) on day 1 for testing with the 2 g and 4 g filaments and on day 3 for testing with all filaments (Fig. 1). Yet, the increase in allodynia following *chromic exposure* was only transient, and by day 5 allodynia was not significantly different than *sham* (Fig. 1). Transient compression produced increases in mechanical allodynia in the ipsilateral forepaw that were sustained (Fig. 1). This increase was significant over *sham* at

Fig. 1 – Average mechanical allodynia in the ipsilateral forepaw for sham (○), chromic exposure (□), 10gf compression (△) and chromic+10gf compression (●). Allodynia is measured by the number of paw withdrawals for stimulation with each von Frey filament: (A) 1.4 g, (B) 2 g, and (C) 4 g. Chromic exposure produced a slight increase in mechanical allodynia that was significant over sham ($p < 0.041$) on day 1 for testing with the 2 g and 4 g filaments and on day 3 for testing with all filaments. By day 5 chromic exposure was not significantly different than sham. Following 10gf compression, ipsilateral allodynia was sustained, displaying significant elevation over sham on day 7 ($p < 0.047$). Chromic+10gf compression produced significant increases in ipsilateral allodynia over chromic exposure ($p < 0.01$), 10gf compression ($p < 0.033$) and sham ($p < 0.043$). Asterisks indicate significant difference between chromic+10gf compression and sham (*), chromic exposure (**) and 10gf compression (***). Pound sign (#) indicates significant difference between 10gf compression and sham, and delta (δ) indicates significant difference between chromic exposure and sham.

days 3 and 5 for testing with the 1.4 g and 4 g filaments and on day 7 for testing with all filaments ($p < 0.047$) (Fig. 1). No significant differences in mechanical allodynia were found between chromic exposure and 10gf compression. However, the combination of compression and chromic gut irritation together

produced a robust increase in allodynia in the ipsilateral forepaw at all time points (Fig. 1). Allodynia for chromic+10gf compression was significantly greater ($p < 0.01$) than that for chromic exposure at all time points with all filaments (Fig. 1). Allodynia for chromic+10gf compression was also significantly greater than that for 10gf compression at days 1 and 3 for all filaments ($p < 0.007$), and at day 5 for testing with the 4g filament ($p < 0.027$) and day 7 for testing with the 2 g filament ($p < 0.033$). Allodynia produced by the combination of insults was also significantly greater than sham at all time points for testing with the 2 g and 4 g filaments ($p < 0.043$), and at days 1 and 3 for testing with the 1.4 g filament ($p < 0.001$) (Fig. 1).

Fig. 2 – Average mechanical allodynia in the contralateral forepaw for sham (○), chromic exposure (□), 10gf compression (△) and chromic+10gf compression (●) for (A) 1.4 g, (B) 2 g, and (C) 4 g von Frey filaments. Chromic exposure and 10gf compression produced slight increases in allodynia over sham. However, chromic+10gf compression produced increased contralateral allodynia compared to sham, chromic exposure and 10gf compression, for testing with the (A) 1.4 g, (B) 2 g, and (C) 4 g filaments. Asterisks indicate significant differences between chromic+10gf compression and sham (*), chromic exposure (**) and 10gf compression (***). Pound sign (#) indicates significant difference between 10gf compression and sham.

Mechanical allodynia was produced in the contralateral forepaw of rats following chemical insult with the chromic gut or transient compression, despite being remote to the injury site. Contralateral mechanical allodynia was not as profound

as that produced on the side ipsilateral to the nerve root injury and was not sustained (Figs. 1 and 2). Nonetheless, contralateral allodynia was slightly elevated over baseline and *sham* for both the *chromic exposure* and *10gf compression* groups, and

Fig. 3 – Representative ipsilateral (B, D, F, H, J, L) and contralateral (C, E, G, I, K, M) C7 spinal cord sections stained against GFAP after *chromic exposure* (B, C, H, I), *10gf compression* (D, E, J, K) or *chromic+10gf compression* (F, G, L, M) on day 1 (B–G) or day 7 (H–M) following injury. A matching normal naive sample (A) was assigned baseline levels of staining. Scale bar shown in panel A is 100 μ m and applies to all panels.

Fig. 4 – Automated densitometry results quantifying percentage of positive pixels reactive for GFAP staining, relative to normal levels at day 1 and day 7 following chronic exposure, 10gf compression, chronic+10gf compression and sham. Significant ($^{\#}p<0.001$) elevations over normal were detected for ipsilateral 10gf compression and chronic+10gf compression at day 1. Ipsilateral 10gf compression was also significantly elevated over sham, chronic exposure, and contralateral expression at day 1 ($^*p<0.022$). All injury groups were elevated in the ipsilateral dorsal horn over normal at day 7 ($^{\#}p<0.044$) with both 10gf compression and chronic+10gf compression also elevated over contralateral expression ($^*p<0.003$). Ipsilateral GFAP staining at day 7 for chronic+10gf compression was significantly greater than the expression at day 1 in the ipsilateral dorsal horn, the expression at day 7 following chronic exposure and the expression at day 7 following sham ($^*p<0.001$).

increased further with the combination of insults (Fig. 2). Chronic exposure produced only mild contralateral allodynia that was not significantly different than sham at any time point. Transient compression produced some significant increases over sham ($p<0.044$) (Fig. 2), but these were inconsistent across von Frey filaments and not sustained. However, the combination of chronic exposure and transient compression increased contralateral allodynia compared to sham, chronic

exposure and 10gf compression (Fig. 2). While the trend was similar to that of the ipsilateral forepaw, contralateral allodynia generally had a slower onset and lower responses (Figs. 1 and 2). A chronic+10gf compression produced significant increases in contralateral allodynia over both chronic exposure and 10gf compression at days 3, 5, and 7, for testing with the 2 g and 4 g filaments ($p<0.039$). These increases were also significant over sham ($p<0.026$) at day 3 for all filaments (Fig. 2).

ID – animal identification number; DH – dorsal horn.

2.2. Spinal glia

Separate groups of rats were used for analysis of glial activation at days 1 and 7 following surgery. Tissue damage during harvest

procedures precluded the use of spinal cord tissue from some rats in the behavioral study. Glial reactivity data at day 7 reflect only a subset of rats used for behavioral assays in each of the *chronic exposure* ($n=4$) and *chronic + 10gf compression* ($n=6$) groups.

Fig. 5 – Representative ipsilateral (B, D, F, H, J, L) and contralateral (C, E, G, I, K, M) C7 spinal cord sections stained against OX-42 after *chronic exposure* (B, C, H, I), *10gf compression* (D, E, J, K) or *chronic + 10gf compression* (F, G, L, M) on day 1 (B–G) or day 7 (H–M) following injury. A matching normal naive sample (A) was assigned baseline levels of staining. Scale bar shown in panel A is 100 μ m and applies to all panels.

2.3. Astrocytic activation

GFAP staining for *chronic exposure* was inconsistent, while staining for *10gf compression* was slightly more robust. The combination of insults increased GFAP staining over normal at day 1 and further at day 7 (Figs. 3 and 4; Table 1). Sham procedures produced only mild bilateral staining or no changes over normal, with only one subject displaying moderate (++) staining and all others displaying baseline (–) or mild (+) staining (Table 1).

At day 1 following *10gf compression* GFAP staining was increased compared to normal, with rats displaying moderate (++) to intense (+++) responses in the ipsilateral dorsal horn. This increase in ipsilateral GFAP staining was significant over normal ($p < 0.001$), as quantified by the densitometry analysis (Fig. 4). This increase was also significant compared to *sham* and *chronic exposure* ($p < 0.022$). However, increases in GFAP following *10gf compression* were observed in the ipsilateral dorsal horn only, and were significant compared to the contralateral dorsal horn ($p = 0.011$), which displayed only mild-to-moderate reactivity (Fig. 4; Table 1). Ipsilateral increases in GFAP staining were maintained at day 7 following *10gf compression* (Fig. 4); densitometry results indicate a significant increase in the ipsilateral dorsal horn over the contralateral dorsal horn and normal at day 7 ($p < 0.003$). GFAP staining at day 7 following *10gf compression* was slightly increased compared to day 1, with rats displaying moderate or intense staining in the ipsilateral dorsal horn.

Chronic exposure produced irregular increases in ipsilateral GFAP staining at day 1 (Fig. 3; Table 1), but this was not significantly different from normal (Fig. 4). At day 7 after *chronic exposure*, ipsilateral staining increased and was significantly elevated over normal ($p = 0.044$) (Fig. 4). Yet, this increase was slight and GFAP staining at day 7 following *chronic exposure*

was significantly lower ($p < 0.001$) than GFAP reactivity produced at day 7 for *chronic+10gf compression* (Fig. 4).

Ipsilateral GFAP staining was robustly increased at day 1 for *chronic+10gf compression*, with rats exhibiting moderate (++) and intense (+++) responses in both the ipsilateral and contralateral dorsal horns (Table 1). Both ipsilateral and contralateral increases in GFAP at day 1 were significant over normal ($p < 0.046$), as quantified by densitometry (Fig. 4). By day 7, ipsilateral GFAP staining following *chronic+10gf compression* was further increased, with a significant elevation over day 1 expression ($p < 0.001$), and the *chronic exposure* ($p < 0.001$), *sham* ($p < 0.001$) and normal ($p < 0.001$) responses (Fig. 4). On day 7, GFAP staining in the ipsilateral dorsal horn was significantly elevated over the contralateral dorsal horn ($p < 0.001$). Semi-quantitative evaluation was graded as intense (+++) in the ipsilateral dorsal horn at day 7 following *chronic+10gf compression* for all but one rat, while contralateral staining was graded as baseline, mild or moderate for this same time point (Table 1).

2.4. Microglial activation

Both ipsilateral and contralateral OX-42 staining were highly variable between rats, with both *chronic exposure* and *chronic+10gf compression* producing a range of scoring from baseline (–) to intense (+++) at each time point (Fig. 5; Table 2). *Sham* responses were consistently at normal levels, with only one subject at each time point displaying mild (+) responses (Table 2). Quantitative results were consistent with the qualitative assessments of variation in OX-42 staining for *chronic exposure* and *chronic+10gf compression*; standard deviations in the densitometry measures were between 27% and 97% of their respective averages (Fig. 6). At day 1, no injury group displayed significant

ID – animal identification number; DH – dorsal horn.

Fig. 6 – Automated densitometry results quantifying relative OX-42 staining at day 1 and day 7 following chromic exposure, 10gf compression, chromic+10gf compression and sham. At day 1, reactivity in the bilateral dorsal horns for all injuries was not significantly different from sham or normal. By day 7, ipsilateral OX-42 staining following 10gf compression or chromic+10gf compression was significantly increased compared to day 1 ($p < 0.001$). These day 7 increases were also significant compared to normal ($\#p < 0.001$), sham ($\#p < 0.001$), and day 7 chromic exposure ($\#p < 0.004$). Contralateral increases were also significant compared to normal following chromic+10gf compression ($\#p = 0.003$) and day 1 chromic+10gf compression ($\#p = 0.008$).

increases in ipsilateral OX-42 staining in the dorsal horn over sham or normal (Fig. 6).

By day 7, ipsilateral staining for chromic exposure remained generally unchanged compared to reactivity at day 1 (Fig. 6; Table 2). In contrast, at day 7 after 10gf compression, ipsilateral OX-42 reactivity was significantly increased compared to day 1 ($p < 0.001$). This ipsilateral increase between days 1 and 7 was also observed following chromic+10gf compression ($p < 0.001$). Increases in ipsilateral OX-42 on day 7 following 10gf compression or chromic+10gf compression were significant over chromic exposure ($p < 0.004$), sham ($p < 0.001$) and normal ($p < 0.001$) (Figs. 5 and 6). In addition, at this later time point, there was no significant difference in OX-42 responses detected between ipsilateral and contralateral dorsal horns for any injury type (Fig. 6). Further, at day 7 the chromic+10gf compression contralateral OX-42 responses were significantly elevated over normal ($p = 0.003$) and the contralateral spinal responses for that same injury at day 1 ($p = 0.008$) (Figs. 5 and 6).

3. Discussion

Many studies have demonstrated a dependence of radicular pain on mechanical and chemical inputs (Kawakami et al., 1994a,b; Kajander et al., 1996; Olmarker et al., 1997; Hashizume et al., 2000; Olmarker et al., 2002; Hou et al., 2003; Winkelstein and DeLeo, 2004; Corneford et al., 2004; Hubbard and Winkelstein, 2005). This study is the first to our knowledge to examine such factors of chemical irritation and nerve root compression for transient loading to the cervical nerve roots. In particular, these results demonstrate a role for transient compression in mediating bilateral mechanical allodynia when combined with chemical factors. While allodynia was produced for chromic exposure, and also for 10gf compression, behavioral hypersensitivity was significantly increased and sustained when these injuries were combined (chromic+10gf compression) (Figs. 1 and 2). Coupled with mechanical allody-

nia, the combination of chemical irritation and transient compression of the nerve root also produced significant increases in both astrocytic and microglial reactivity in the dorsal horn of the spinal cord at day 7 (Figs. 4 and 6).

Although the combination of chromic gut exposure and transient compression induced robust increases in mechanical allodynia, chromic exposure alone also produced significantly elevated ipsilateral mechanical allodynia over sham at early time points. Allodynia following chromic exposure returned to sham levels by day 5 (Fig. 1), despite the fact that the chromic gut pieces remained in contact with the nerve root for the duration of the study. These results are in agreement with previous studies demonstrating slight and non-sustained increases in behavioral hypersensitivity following chromic exposure or a loose ligation of chromic suture around the lumbar nerve root (Lee et al., 2003; Winkelstein and DeLeo, 2004). Maves et al. (1993) demonstrated a 'dose response' for thermal sensitivity from sciatic nerve ligations using chromic gut suture; it is, therefore, likely that the amount or diameter of suture used in our study may not have been sufficient to induce a sustained behavioral effect. However, in studies using a chromic gut ligation it is difficult to separate the respective roles of the inflammatory and mechanical effects. The chromic gut suture can resorb and ligation with this material may induce further tightening as a consequence of tissue swelling, with both effects changing the local mechanics over time. Some studies of low back pain have utilized what those authors defined as a 'loose' ligation of the nerve root to place chromic suture in contact with the nerve root without applying additional pressure and a 'tight' ligation to apply mechanical compression in addition to the chemical irritation of the chromic suture (Kawakami et al., 1994a; Hashizume et al., 2000; Rutkowski et al., 2002). While described as 'loose' and 'tight' respectively, the mechanical conditions of the ligation groups were not explicitly defined by those authors. Yet, it is likely that the 'loose' chromic ligation did impose mechanical loading since gross pathology demonstrated narrowing in the nerve

root following ‘loose’ ligations (Kawakami et al., 1994b; Hashizume et al., 2000). In our study, it is possible that the chronic gut pieces may have also imposed physical irritation to the nerve root, but this is very unlikely. The chronic pieces contacted the nerve root when gently placed along the root. They are very small and have little mass to provide any direct compression. In addition, visual inspection of the root at the time of tissue harvest showed no evidence of its narrowing or deformation in samples from the *chronic exposure* group.

The increased behavioral hypersensitivity for the combination of insults compared to a single insult (Figs. 1 and 2) is consistent with other reports of increases in mechanical and thermal hyperalgesia when these insults are combined compared to the application of disc material without compression of the root (Olmarker et al., 1997; Hou et al., 2003). Results presented here demonstrate that the combination of mechanical and chemical factors induces allodynia that is robustly increased compared to either chemical or mechanical injury alone (Figs. 1 and 2). Findings also suggest that a mechanical insult may be required for behavioral symptoms to be chronic, as chemical irritation alone does not produce sustained allodynia while the transient compression produce allodynia that is significant at day 7. Our data lend additional support to the hypothesis that the load threshold for producing persistent hypersensitivity in nerve root compression is lowered when chemical factors are present at injury (Winkelstein and DeLeo, 2004).

While bilateral allodynia has been previously reported for a unilateral insult (Tabo et al., 1999; Rutkowski et al., 2002; Araujo et al., 2003; Hou et al., 2003; Hubbard and Winkelstein, 2005), such mirror-image behavioral hypersensitivity was only significant for the combined mechanical and chemical insult (Fig. 2). This production of contralateral allodynia for a combined injury could imply that functional changes in the spinal cord are specifically induced in the interneurons that project to the non-operated contralateral side only for specific injury paradigms and not for the chemical or mechanical injuries used in this study. Contralateral sensitivity has been previously reported for the combination of these insults, but not for exposure of the nerve root to chronic material or intervertebral disc samples (Maves et al., 1993; Rutkowski et al., 2002; Hou et al., 2003). Although contralateral allodynia has been induced by mechanical insults in the absence of any chemical loading, those studies implemented either ligation of multiple nerve roots or the spinal nerve, imposing a more severe sustained mechanical compression and one which may induce either a more robust, or continuous, barrage to the nociceptive cascades (Tabo et al., 1999; Araujo et al., 2003). While we did not specifically probe electrophysiologic properties of spinal interneurons, neuronal sensitization in the spinal cord can be initiated by increased neurotransmitter release, inflammatory cytokines, or directly by glial cells (Schiefer et al., 1999; Tabo et al., 1999; Cuellar et al., 2004; Inoue, 2005; Tsuda et al., 2005). Ipsilateral astrocytic activation was present at day 7 following compression and was further increased for the combined injury (Figs. 3 and 4; Table 1). Microglial activation at day 7 was also increased following compression, but was only on the side of injury; in contrast, for the addition of chronic suture, microglial reactivity at day 7 was observed bilaterally in the spinal cord (Figs. 5 and 6; Table 2). These increases in spinal glial activation following the com-

bined injury at day 7 compared to either mechanical or chemical injuries alone imply that spinal inflammation is greatly increased when these factors are combined. Robust bilateral spinal inflammation, including increases in cell surface markers and inflammatory cytokines, and behavioral hypersensitivity have been reported for chronic ligation of lumbar nerve roots further supporting a role for inflammation in mediating spinal glial responses in painful nerve root injury (Rutkowski et al., 2002). Biochemical and functional immune changes in the spinal cord correlate with mechanical parameters for nerve root loading (i.e. applied loading rate, magnitude and duration); for example, imposed nerve root strain is significantly correlated with spinal mRNA levels for a host of inflammatory cytokines, implying sensitive biochemical responses to mechanical nerve root injury (Winkelstein et al., 2001a,b). Further, there is a direct relationship between root compression and neuronal function (Olmarker et al., 1989, 1990; Pedowitz et al., 1992; Mao et al., 1998; Yamaguchi et al., 1999). These results provide a host of candidate spinal responses that may be induced by injuries to the nerve root and are likely sensitive to the specific profile of the mechanical injury.

In the current study, the time course of activation of astrocytes and microglia was differentially modulated for the three types of injuries. At day 1, spinal astrocytic activation was evident in the ipsilateral horn for *10gf compression* and *chronic+10gf compression*, with an increase in activation on that side at day 7 following the combined injury (Fig. 4). However, microglial activation was not significantly elevated until day 7, and it was bilateral (Fig. 6). This is consistent with results from studies using silk ligations in which microglial activation was bilateral, whereas astrocytic activation was only apparent on the ipsilateral side of the spinal cord (Winkelstein and DeLeo, 2002). Bilateral increases in microglia, but not astrocytes, may be produced because microglia are more sensitive to ionic changes caused by neuronal sensitization which may occur on the contralateral side. Although little is known about what triggers glial activation, it has been shown that both microglia and astrocytes can be activated by depolarization of neighboring neurons, consistent with a tetrapartite model of the synapse (Kreutzberg, 1996; DeLeo et al., 2006). Yet, microglia may respond to these neuronal changes before astrocytes, and may be more sensitive to changes in neurotransmitters (Caggiano and Kraig, 1996). It is likely that in our combined injury microglia in the contralateral dorsal horn respond to small perturbations in extracellular ion homeostasis and this microglial activation then leads to further neuronal sensitization. Astrocytic activation may be present in the contralateral dorsal horn at a time point not probed in this study, as microglia produce and release molecules that can cause astrocytic activation (Kreutzberg, 1996; Newman, 2003; DeLeo et al., 2006). Studies of kinase activation and transcriptional changes demonstrate that spinal microglial activation can precede astrocytic activation (Tanga et al., 2004; Zhuang et al., 2005). While this study did probe the time course of glial activation, additional studies are needed of both acute and intermediate time points not studied here.

Differential spinal glial activation may also result from these cells having different thresholds for activation. Spinal astrocytic activation after ligation using silk is only slightly

lower than that for a ligation with chromic gut (Hashizume et al., 2000; Winkelstein and DeLeo, 2002). This suggests that the initiation of spinal astrocytic reactivity may require a mechanical insult, and that it is only enhanced when this mechanical injury is accompanied by a chemical insult. In contrast, in those models, spinal microglial activation was greater for ligation with chromic suture relative to silk, suggesting that spinal microglia are responsive to chemical irritation. Microglial reactivity in our study increased bilaterally between days 1 and 7 for *chromic+10gf compression*, and unilaterally following compression alone (Fig. 6; Table 2), suggesting that microglia respond sensitively to the type and intensity of injury. Results presented here demonstrate only moderate microglial activation following *chromic exposure* (Fig. 6; Table 2) implying that it is the combination of insults, rather than simply a chemical insult alone, that causes robust microglial activation.

Our results, in the context of other studies, imply that microglia are more sensitive to chemical inputs than astrocytes are. This is in agreement with studies demonstrating that microglia respond to minor changes in their environment (Caggiano and Kraig, 1996; Kreutzberg, 1996). The apparent disparity in responses between microglia and astrocytes for different types of stimuli may be due to their varying roles in the central nervous system. Activated microglia release cytokines (TNF α , IL-1 β , IL-6), which can then activate astrocytes, and also induces changes in neuronal excitability, as well as transcriptional changes in neurons that alter their sensitivity to stimuli (McMahon et al., 2005). The findings presented here are contradictory to this, with astrocytic reactivity significantly elevated over normal at day 1 following *chromic+10gf compression* and microglia not exhibiting significant elevations until later at day 7 (Figs. 4 and 6). However, it is possible that the peak of microglial activation precedes the peak of astrocytic activation and occurs at an intermediate time point not probed in this study. In fact, following a painful lumbar nerve ligation, spinal extracellular signal-regulated protein kinases are activated in microglia with maximum activation on day 2, followed by a peak of pERK activation in astrocytes at day 21 (Zhuang et al., 2005). The bilateral microglial activation produced at day 7 for *chromic+10gf compression* indicates prolonged microglial reactivity when chemical irritation is combined with transient compression in our model (Fig. 4). This could also suggest sustained cytokine release in a combined mechanical and chemical injury.

While our results demonstrate that the combination of putative insults causes robust and widespread behavioral and spinal glial responses (Figs. 1–6), additional studies directed at specific mechanical and chemical dose-effects are needed to fully define the relationship between injury parameters and pain. Although the present study used a repeatable, reliable chemical irritation as a discrete and uniform amount of chromic gut suture, the precise chemicals delivered and their effect on behavioral sensitivity were not specifically identified here. Quantitative studies specifically probing the role of spinal glia and their biochemical contributions, such as cytokine production, for different degrees of painful mechanical and/or chemical injury are necessary at additional time points. While the time points in this study were chosen as the onset and maintenance of behavioral hypersensitivity in this

cervical radiculopathy model (Hubbard and Winkelstein, 2005; Rothman et al., 2005), it may be necessary to examine microglial activation at other time points. Further, it is recognized that qualitative microglial activation data showed a wide range of variability (Table 2) and associated densitometry results showed correspondingly highly standard deviations (Fig. 6); larger group sizes may also be necessary. While exposure of the nerve root to chromic gut suture does not directly mimic the clinical condition of nerve root irritation by the disc material, the chromic salts and pyrogallol that are used to produce chromic suture are known to be inflammatory to nervous tissue (Maves et al., 1993). Chromic suture, therefore, provides a basis for modeling the chemical component of painful disc herniation. In fact, chromic gut suture has been used extensively in models of low back pain to mimic the inflammatory effects of disc material (Kawakami et al., 1994a, b; Maves et al., 1993; Hashizume et al., 2000; Rutkowski et al., 2002; Lee et al., 2003; Winkelstein and DeLeo, 2004). These models also demonstrate a robust increase in behavioral hypersensitivity for chromic ligations (mechanical and chemical injury) compared to a mechanical ligation injury alone (Kim and Chung, 1992; Kawakami et al., 1994b; Hashizume et al., 2000), similar to the behavioral effects achieved by applying nucleus pulposus directly to the compressed nerve root (McCarron et al., 1987; Hou et al., 2003; Kawakami et al., 2003; Murata et al., 2004; Kallakuri et al., 2005). Further, behavioral outcomes from both chromic suture ligation and disc herniation models are similar to clinical symptoms from disc herniation, which show long-term sensitivity in the extremities (Ellenberg et al., 1994; Boos et al., 1995).

These results demonstrate that either chemical irritation or mechanical compression to the cervical nerve root can induce mechanical allodynia and spinal glial activation and that those responses are increased by the combination of these insults. Behavioral results from our study support that pain can be produced in the absence of a compression (Figs. 1 and 2). However, while chemical irritation alone may be responsible for some pain cases, a compressive event, even a transient one, can dramatically enhance behavioral sensitivity and such sensitivity may persist. Microglial activation was highly variable both between injury types and for individual rats in each injury group (Table 2); this may explain, in part, the individual variation in pain symptoms observed for humans. Studies are needed to specifically define the relationships between mechanical and chemical parameters and behavioral, cellular, and biochemical responses in quantitative approaches.

4. Experimental procedure

Experiments were performed using male Holtzman rats (Harlan Sprague-Dawley; Indianapolis, ID), weighing 250–350 g at the start of the study. Rats were housed under USDA- and AAALAC-compliant conditions with a 12-h:12-h light/dark cycle and free access to food and water. All experimental procedures were approved by the University of Pennsylvania Institutional Animal Care and Use Committee and carried out according to the guidelines of the Committee for Research and Ethical Issues of the IASP (Zimmermann, 1983).

4.1. Surgical procedures

All procedures were performed under inhalation anesthesia (4% halothane for induction, 2% for maintenance). Each rat received either nerve root exposure to chromic gut suture material (*chromic exposure*) ($n=10$), transient nerve root compression (10gf compression) ($n=8$), chromic gut exposure with supplemental cervical nerve root compression (*chromic+10gf compression*) ($n=13$), or sham exposure (*sham*) ($n=6$). For this study, previously described procedures of cervical dorsal root compression were used and modified to incorporate inflammatory components at the time of insult (Hubbard and Winkelstein, 2005; Rothman et al., 2005). Rats were placed in a prone position, and an incision was made in the skin from the base of the skull to the second thoracic vertebra. Muscle and soft tissue were cleared exposing the C6 and C7 laminae. A C6/C7 hemilaminectomy and partial facetectomy were performed on the right side to expose the spinal cord and right C7 dorsal nerve root. Procedures for the *chromic exposure* involved placing four pieces of 3-0 chromic gut suture (2 mm in length) (Surgical Specialties; Reading, PA) on the right C7 dorsal nerve root proximal to the dorsal root ganglia (DRG). Procedures for 10gf compression match those previously published (Hubbard and Winkelstein, 2005; Rothman et al., 2005). Briefly, a 10gf microvascular clip (World Precision Instruments, Inc) was applied to the right C7 dorsal nerve root proximal to the dorsal root ganglion. Compression was imposed for 15 min, before clip removal. Procedures for *chromic+10gf compression* involved those described for *chromic exposure* in addition to those described for 10gf compression. Compression was applied to the right C7 dorsal nerve root proximal to the DRG, removed after 15 min, and then four chromic gut suture pieces were placed on the dorsal root as described above. Procedures for *sham* involved nerve root exposure only, as previously published (Rothman et al., 2005). Following surgery, all wounds were closed using 3-0 polyester suture and surgical staples. Rats were recovered in room air and monitored continuously.

4.2. Behavioral assessment

Following surgery, a subset of rats ($n=6$ *chromic exposure*, $n=4$ 10gf compression, $n=7$ *chromic+10gf compression*, $n=3$ *sham*) was evaluated for behavioral hypersensitivity after injury. Mechanical allodynia was measured in the ipsilateral and contralateral forepaws on each of postoperative days 1, 3, 5, and 7. Methods for quantifying forepaw allodynia have been previously validated for cervical nerve root injury (Hubbard and Winkelstein, 2005; Rothman et al., 2005). Prior to surgery, rats were acclimated to the tester and environment, and baseline measurements were recorded for 2 days. For each session, after 20 min of acclimation, rats were stimulated on the plantar surface of the ipsilateral and contralateral forepaws, separately, using three von Frey filaments (1.4, 2, 4 g) (Stoelting Co.; Wood Dale, IL). Each testing session consisted of three rounds of 10 stimulations each to each forepaw, separated by 10 min. For each session with a given filament, the total number of withdrawals was counted for each paw and averages for each injury group were determined. A single tester performed all behavioral testing blinded to surgical procedures.

4.3. Immunohistochemistry procedures

In order to assess the temporal pattern of glial activation in the dorsal horn, C7 spinal cord was assayed for astrocytic and microglial activation using antibodies to glial fibrillary acidic protein (GFAP) and CR3/CD11b (OX-42), respectively. Cervical spinal cord tissue was harvested on each of days 1 and 7 following injury. Spinal cord tissue evaluated at day 1 was taken from a separate set of rats than that used for allodynia assessments ($n=4$ *chromic exposure*, $n=4$ 10gf compression, $n=6$ *chromic+10gf compression*, $n=3$ *sham*). For tissue harvest, rats were deeply anesthetized followed by transcardiac perfusion with 200 ml of phosphate-buffered saline (PBS) and 300 ml of 4% paraformaldehyde in PBS (pH 7.4). Following perfusion, the cervical spinal cord was exposed by laminectomy, the C7 segment of the cervical cord was harvested, and tissue was post-fixed in the 4% paraformaldehyde solution for 20 min (Hubbard and Winkelstein, 2005). Tissue was transferred to 30% sucrose/PBS and stored for 3 days at 4 °C. Samples were freeze-mounted with OCT medium (Triangle Biomedical Sciences; Durham, NC) for axial cryosectioning. Matched spinal cord tissue from a naïve (un-operated) rat was also processed for normalization and comparison.

Four serial C7 spinal cord sections (20 μ m) from each rat were prepared for free-floating immunohistochemical staining. A polyclonal antibody to GFAP (Dako; Carpinteria, CA) was used as a marker of activated astrocytes. Slices were blocked with normal goat serum (Vector Labs; Burlingame, CA) for 20 min followed by incubation in a primary antibody directed against GFAP (1:20,000) overnight. Sections were then treated with a biotinylated goat anti-rabbit IgG, quenched in 0.3% peroxide solution, and developed using 3,3'-diaminobenzidine (Vector Labs; Burlingame, CA). For a second set of matched axial sections, a monoclonal antibody to CR3/CD11b (OX-42; BD Pharmingen; San Diego, CA) was used as a marker of activated microglia. Spinal cord slices were blocked with normal goat serum (Vector Labs; Burlingame, CA) for 20 min and incubated overnight in an antibody directed against OX-42 (1:500). An Alexa546-conjugated goat anti-mouse secondary antibody (1:500) was used for immunofluorescent detection (Invitrogen; Carlsbad, CA). Previous studies were performed to determine optimal antibody dilutions. A negative control with no primary antibody staining was always included for verification of specificity of immunohistochemical techniques.

Two techniques were used to analyze glial activation. Semiquantitative scoring was used to grade the glial activation in each of the ipsilateral and contralateral dorsal horns to enable comparison to normal sections and results in the literature. In addition, automated densitometry was also used to quantify staining to enable quantitative and statistical comparisons. For each glial marker, two representative cord sections from each rat were photographed at 100 $\times$ magnification using a digital camera and stereomicroscope system and Axiovision software (Zeiss; Thornwood, NY). For both analysis methods, the ipsilateral and contralateral dorsal horns relative to the injury site were assessed. For the semi-quantitative grading, two observers, blinded to the injury group graded the degree of activation. Separate scores were given to ipsilateral and contralateral sides. Grading was performed using an established 4-point scale, based on cell numbers, compactness, and intensity of staining (Colburn

et al., 1999; Winkelstein and DeLeo, 2002; Hubbard and Winkelstein, 2005). Assessments were made using the following levels of gradation: baseline staining (–), mild response (+), moderate response (++), and intense response (+++) (Colburn et al., 1999). Results from the first observer were verified by the second observer, and tabulated. For automated densitometry analysis, the same sections were used for semi-quantitative scoring. Images were cropped (800×200 pixels) to include the superficial lamina I–III only; fluorescent images were also inverted. Images were analyzed for percentage of pixels above a defined threshold (Abbadie et al., 1996). Threshold pixel intensity was chosen based on staining in normal tissue. This approach gives a quantitative measure of the degree and amount of staining above what is present in normal naïve tissue. Values were normalized, averaged and compared.

4.4. Statistical analysis

Significant differences in allodynia between groups were detected by a one-way ANOVA at each time point (SYSTAT; Richmond, CA). For quantitative densitometry, a one-way ANOVA was performed to compare differences over time (day 1, day 7), between injury groups (chronic exposure, 10gf compression, chronic+10gf compression, sham), and between sides of the spinal cord (ipsilateral, contralateral). Significance was defined at $p < 0.05$.

Acknowledgments

The authors thank Dr. Steven B. Nicoll for use of his microscope and imaging system and Raymond D. Hubbard for assessment of glial activation.

This work was funded by grant support from NIH (NIAMS) AR047564-02 and the Catharine D. Sharpe Foundation.
