Co-evolution Is Incompatible With the Markov Assumption in Phylogenetics

Abstract
Markov models are extensively used in the analysis of molecular evolution. A recent line of research suggests that pairs of proteins with functional and physical interactions co-evolve with each other. Here, by analyzing hundreds of orthologous sets of three fungi and their co-evolutionary relations, we demonstrate that co-evolutionary assumption may violate the Markov assumption. Our results encourage developing alternative probabilistic models for the cases of extreme co-evolution.

Markov models are extensively used in the analysis of molecular evolution. A recent line of research suggests that pairs of proteins with functional and physical interactions co-evolve with each other. Here, by analyzing hundreds of orthologous sets of three fungi and their co-evolutionary relations, we demonstrate that co-evolutionary assumption may violate the Markov assumption. Our results encourage developing alternative probabilistic models for the cases of extreme co-evolution.

Markov models have been extensively used in studies and modeling of molecular evolution (see, for example, [1-11]). The Markov assumption is very natural: stating that the statistical distribution of nucleotides in different positions of a gene is determined by their distribution in the corresponding gene of its direct ancestor with no effect of older ancestors (Figure 1A).
Let $X_i^k$ denote a random variables corresponding to the value of the $k$-th nucleotide at a given site at node (taxa) $i$. Let $x_i^k$ denote a particular state (nucleotide) of the random variable $X_i^k$.

By the Markov assumption, if $X_1^k$ is the direct ancestor of $X_2^k$, and $X_2^k$ is the direct ancestor of $X_3^k$, the following is true:

$$p(X_3^k | X_2^k, X_1^k) = p(X_3^k | X_2^k)$$

We say that two sites, $X_i^{k_1}$ and $Y_i^{k_2}$, co-evolve if evolutionary change at one site is influenced by the evolution of the second site. Mathematically it means that there is information flow between $X_i^{k_1}$ and $Y_i^{k_2}$ (i.e. the joint distribution of $X_i^{k_1}$ [or $Y_i^{k_2}$] depends on both $X_i^{k_1}$ and $Y_i^{k_2}$, see Figure 1B).

A recent line of research suggests that different sites within or between proteins functionally and physically interact and thus, co-evolve (see, for example, [12-17]).

As can be seen in Figure 1B, if site $X_i^{k_1}$ co-evolves with site $Y_i^{k_2}$ there may be an information flow between $X_3^{k_1}$ and its indirect ancestor $X_1^{k_1}$, not via $X_2^{k_1}$.

Thus, mathematically, under such a realistic assumption, a site in a certain node (taxon) in the evolutionary tree may depend on the value of its corresponding indirect ancestors even when conditioning on its direct ancestor, contradicting the Markov assumption (Figure 1B).
To demonstrate this point, we analyzed the conserved coding sequences of three close fungi (Figure 1C; Methods); we aimed at performing a statistical test that checks the Markov assumption without any additional assumptions on the nature or parameters of the process. Specifically, we computed a measurement that is related to 

$$\frac{p(X_{3} | X_{2}, X_{1}) - p(X_{1} | X_{2})}{p(X_{3} | X_{1})}$$ (i.e. it measures the relative skew from the Markov assumption considering three nodes in the evolutionary tree; see more details in the Methods).

We found a significant positive relation between the skew from the Markov assumption and the density of co-evolutionary relations (the number of co-evolutionary relations of a gene normalized by its length; see technical details in the Methods) - more co-evolutionary interactions per nucleotide implies larger skew from the Markov assumption. Specifically, when we compared the 15% of the genes with top co-evolutionary density to the 15% of the genes with the bottom co-evolutionary density we found that the first group has significantly higher mean skew from the Markov assumption (T-test – p value = $6.5 \times 10^{-5}$, KS test p value = $3 \times 10^{-6}$). In addition, we found significant Spearman correlation between co-evolutionary densities and skew from the Markov assumption across all genes ($r = 0.15$, $p = 2.8 \times 10^{-4}$; Spearman correlation, 10 bins with equal size, each with 10% of the genes: $r = 0.84$, $p = 0.002$; Figure 1C). The correlation remained significant even when we controlled for the conservation of the genes ($r = 0.134$; $p=0.001$; Methods) demonstrating that different mutation rate between genes can not explain the correlation.
Our results suggest that co-evolution introduces memory to the process of molecular evolution. Moreover, the density of co-evolutionary relations of a gene is inversely related to how well a Markov model approximates its evolution.

Previous studies have shown (based on simulation and analytical analysis) that skew from Markovity can cause erroneous phylogenetic reconstruction [18, 19] and increase the error rate in ancestral reconstruction [12]. Thus, we should expect higher error rate when we use Markovian models to analyzed genomic sequences that have many co-evolutionary relations. In addition, our results encourage developing/using alternative probabilistic models for the cases of extreme co-evolution; one possible alternative probabilistic model might be a hidden Markov model (Figure 1D) where the hidden variables represent the interaction between the protein/site and other proteins/sites.

![Figure 1](image)

**Figure 1.** A. The traditional model of molecular evolution is Markovian; each arrow represents the information flow from an ancestor to its descendant. The value of a
node does not depend on its 'grandparent' given its direct parent. B. A model of molecular evolution under co-evolution; the dashed arrows represent co-evolutionary relations. Red arrows are used to show the route by which information may 'flow around' an immediate ancestor. The fact that two proteins/sites co-evolve and thus they are dependent implies that the value of a node may depend on its grandparent given its direct parent. C. The skew from Markovity, measured by analyzing the coding sequences of three fungi, increases with the density of co-evolutionary relations (10 bins of equal size, 10% of the genes, of co-evolutionary density vs. the skew from Markovity); the correlation between the mean co-evolutionary density and Markovity is significantly higher for the 15% of the genes with the highest co-evolutionary density compared to the 15% of the genes with the lowest co-evolutionary density (KS test p value = $3 \times 10^{-6}$). D. An illustration of probabilistic model that may better describe the evolution of a single site or a protein under extensive co-evolution.

Finally, it is important to mention that co-evolution is not the only possible cause of non-Markov behavior. For example, it was suggested before that when the substitution rates vary across sites the entire probabilistic process becomes non-Markovian [18]. It is easy to see that co-evolution and varying substitution rates are not independent phenomena (Figure 2): proteins that physically interact with each other tend to co-evolve ([12, 13, 20]; Figure 2A); in these proteins, the sites that are involved in the interactions are expected to have less substitutions as they are under more constraints (Figure 2B). Thus, co-evolution can induce varying substitution rates. There are many additional possible reasons that may cause a skew from
Markovity; some of them are the functionalities of different parts of the proteins (that may have different substitution rates), the position within a codon (it is known that the third positions are less conserved [18]), the fact that different regions (e.g. the beginning of the coding region [21, 22]) correspond to the regulation of its translation [21, 22] and thus may have different substitution rate.

Figure 2. An illustration describing how co-evolution can imply varying substitution rate across characters. A. The proteins A and B physically interact with each other and thus they co-evolve. The interacting sites within each protein are marked in black. B. The substitution rates in the non interacting sites (r1,...,r4) and in the interacting sites (r'1,...,r'4) of protein A – the non interacting sites are under less evolutionary constraints and thus have higher substitution rate.
Methods:

Sets of orthologs: The sequences of the three Fungi (S. paradoxus, S. cerevisiae, and S. bayanus) and mapping of genes to groups of orthologs were downloaded from [23]. We considered sets of orthologs that do not include duplicates (according to COG [24]) and whose level of conservation (percentage of the sites that are identical in the three Fungi) is above 30%. The final dataset included 598 sets of orthologs.

Alignment: We aligned each set (of three coding sequences) using CLUSTALW [25]. Specifically, for each set, we translated the three sequences to Amino Acids; align them, removed gaps, and converted the result amino acid sequences to an aligned set of nucleotide sequences.

Co-evolution relations: The co-evolutionary information (based on a composite score that is based on co-expression, co-occurrences in the same genome, genomic proximity, protein-protein interaction, and more) was downloaded from STRING [26]. We mapped the S. cerevisiae gene in each set to a corresponding COG; the number of relations of the COG in STRING was used as an estimator of the level of co-evolution for the set of orthologs. To compute the density of the co-evolutionary relations we divided this number by the length of the alignment.

The phylogenetic tree: We used the phylogenetic tree of [27].

Estimating the values at the ancestors of S. paradoxus: To study how the Markov property relates to co-evolution we are interested in Markov chains of length three (e.g. S. paradoxus, the direct ancestor of S. paradoxus, and S. bayanus – that was used as an indirect ancestor of S. paradoxus under Bayes rule; Figure 1C). In our analysis, we do not know the actual values at the direct ancestor of S. paradoxus. However, the branch connecting S. cerevisiae to the ancestor of S. paradoxus is
relatively short (the edge length is 0.015; see [27]): it is more than 3 times shorter than the other branches to the leaves in the analyzed tree; it is also much shorter (at least 3 times shorter, many times more than 7 times shorter) than all the branches to the 42 Fungi that appear in the original tree (see Figure 2 in [27]).

Thus, we used the value at the genome of *S. cerevisiae* as an estimator for the values at the direct ancestors of *S. paradoxus*. It is important to emphasize that in this paper we show that our measure of skew from the Markov property (that is based on the assumption that the edge length above is very short and thus may be noisy) is correlated with the density of co-evolutionary relations. This correlation can not be explained by the noise in our measure (if the noise is not related to co-evolution).

In addition, based on Bayes' law (or assume a reversible stochastic model, see, for example, [28]) we use *S. bayanus* as indirect ancestor of *S. paradoxus*. Note that the same assumptions and approximations were made for all the genes (*i.e.* both for genes with high density of co-evolutionary relations and the genes with low density of co-evolutionary relations).

**Checking for the Markov property:** We design a statistical test to estimate the Markov property; the test does not require any additional assumptions on the nature or parameters of the process.

For a certain set of orthologs, let $x_3^{k_1}, x_3^{k_2}$ denote the values at two sites in a gene of *S. paradoxus*; let $x_2^{k_1}, x_2^{k_2}$ denote the values at the corresponding sites at the direct ancestor of *S. paradoxus*, let $x_1^{k_1}, x_1^{k_2}$ denote the value at the corresponding sites of the indirect ancestor of *S. paradoxus*. 
Under the Markov property, the statistical distribution of nucleotides in different positions of a gene is determined by their distribution in the corresponding gene of its direct ancestor with no effect of older ancestors. In our case, we assume only the three organisms mentioned above [the organisms for which the required data were available and which satisfied our assumption about the edge lengths].

We aimed at comparing

\[ \Pr[x_3^{k_1} = x_2^{k_2} | x_2^{k_1} = x_2^{k_2}] \text{ and } \Pr[x_3^{k_1} = x_2^{k_2} | x_2^{k_1} = x_2^{k_2}, x_1^{k_1} = x_1^{k_2}] \]

For a Markov model we expect that (1) will be equal to (2) but for a non-Markovian case we expect that (2) will be larger than (1).

Let \( \delta(\cdot) \) denote the indicator function; for a certain gene, these values were estimated by the following equations:

First, we considered all the pairs of sites that are identical at the direct ancestral gene and computed the fraction of times that the corresponding pair of sites at the gene is also identical (i.e. this is the empirical probability that a pair of sites are identical given that they are identical at the direct ancestral gene).

\[
(3) \quad I_{3,2} = \frac{\sum_{k_1,k_2} \delta(x_3^{k_1} = x_3^{k_2}, x_2^{k_1} = x_2^{k_2})}{\sum_{k_1,k_2} \delta(x_2^{k_1} = x_2^{k_2})}
\]

Second, we considered all pairs of sites that are identical both in the direct ancestral gene and in the indirect ancestral gene and computed the number of times
corresponding pair of sites at the gene is also identical (i.e. this is the empirical probability that a pair of sites are identical given that they are identical at the direct and indirect ancestral gene).

\[
I_{3,2,1} = \frac{\sum \delta(x_3^{k_1} = x_3^{k_2}, x_2^{k_1} = x_2^{k_2}, x_1^{k_1} = x_1^{k_2})}{\sum \delta(x_2^{k_1} = x_2^{k_2}, x_1^{k_1} = x_1^{k_2})}
\]

By the markovian assumption (if the direct ancestor is known information about the indirect ancestor should not help determining the value at the current site) we do not expect that (4) will be larger than (3). Thus, we used (5) \((I_{3,2,1} - I_{3,2}) / I_{3,2}\) to estimate the skew from the Markov property in each gene.

It is known that proteins with more co-evolutionary relations are more conserved [29]. Let, \(|x|\) denote the length of the sequence (gene) \(x\); let \(C = \sum_{x} \delta(x_i^{k} = x_i^{k} = x_i^{k}) / |x|\) denote the conservation level of a gene \(x\) (in our case, the fraction of the sites in \(x\) that are conserved in the three Fungi that we analyzed). In our dataset, the correlation between \(C = \sum_{x} \delta(x_i^{k} = x_i^{k} = x_i^{k}) / |x|\) and the number of co-evolutionary relations is 0.135; \(p = 0.0008\). Thus, we used \(C\) as a covariate variable in the partial correlation between the density of co-evolutionary relations and the skew from Markovity.

In addition, to control for the fact that conservation of proteins with high co-evolutionary relations is higher [29] and as we are interested in the statistical nature of the phenomenon and not in its biological/functional nature we considered only pairs
\( k_1 \) and \( k_2 \) for which \( x_1^{k_1} = x_3^{k_2}, x_2^{k_1} = x_2^{k_2}, x_3^{k_1} \neq x_2^{k_1} \) and applied this restriction to the numerator and denominators of (3) and (4).
