Parallel Composition of Templates for Tail-Energized Planar Hopping

Abstract
We have built a 4DOF tailed monoped that hops along a boom permitting free sagittal plane motion. This underactuated platform is powered by a hip motor that adjusts leg touchdown angle in flight and balance in stance, along with a tail motor that adjusts body shape in flight and drives energy into the passive leg shank spring during stance. The motor control signals arise from the application in parallel of four simple, completely decoupled 1DOF feedback laws that provably stabilize in isolation four corresponding 1DOF abstract reference plants. Each of these abstract 1DOF closedloop dynamics represents some simple but crucial specific component of the locomotion task at hand. We present a partial proof of correctness for this parallel composition of “template” reference systems along with data from the physical platform suggesting these templates are “anchored” as evidenced by the correspondence of their characteristic motions with a suitably transformed image of traces from the physical platform.

Parallel Composition of Templates for Tail-Energized Planar Hopping

Avik De* ● Daniel E. Koditschek*

Abstract—We have built a 4DOF tailed monoped that hops along a boom permitting free sagittal plane motion. This underactuated platform is powered by a hip motor that adjusts leg touchdown angle in flight and balance in stance, along with a tail motor that adjusts body shape in flight and drives energy into the passive leg shank spring during stance. The motor control signals arise from the application in parallel of four simple, completely decoupled 1DOF feedback laws that provably stabilize in isolation four corresponding 1DOF abstract reference plants. Each of these abstract 1DOF closed loop dynamics represents some simple but crucial specific component of the locomotion task at hand. We present a partial proof of correctness for this parallel composition of “template” reference systems along with data from the physical platform suggesting these templates are “anchored” as evidenced by the correspondence of their characteristic motions with a suitably transformed image of traces from the physical platform.

I. INTRODUCTION

The control of power-autonomous, dynamic legged robots that have a high number of degrees of freedom (DOF) is made difficult by a number of factors including (a) underactuation necessitated by power-density constraints, (b) the existence of significant inertial coupling and Coriolis forces that are hard or impossible to cancel, (c) variable ground affordance, (d) often hard-to-measure and necessarily rapid hybrid transitions. In the face of these challenges, some popular methods of controller design, such as hybrid zero dynamics [1]—which are “exact” in their domain of applicability but require extremely accurate qualitative and quantitative models—may be challenging to implement in unstructured environments or on imperfectly characterized machines. Similarly, methods depending on local linearizations of the typically (highly) nonlinear dynamics found in dynamically dexterous locomotion and manipulation systems [2], [3] typically suffer from small basins of attraction [4] and (to our knowledge) high sensitivity to parameters.\(^1\)

Observation (a) suggests that modularity of operation (i.e., wherein different combinations of actuators are used to effect distinctly different dynamical goals at different stages within the task cycle) will be a hallmark of practical locomotion platforms. Observations (b) and (c) imply that simpler, less exact but potentially more robust representations of the principal dynamical effects likely to prevail across a wide range of substrates may offer a tractable means of working with rather than fighting against, or learning exactly the highly varied dynamical details. Observation (d) implies that higher authority sensorimotor control activity ought to target continuous phases of the locomotion cycle, leaving the transition event interventions to more passive and mechanical sources of regulation [6]. In sum, these observations motivate the search for modular, reduced order representations of locomotion task constituents that are specialized to couple selected actuation affordances to particular DOFs at particular phases of the locomotion cycle. The value of such component task representatives remains hostage to the availability of methods for composing them in a stable manner.

This report introduces a novel locomotion platform, the Penn Jerboa, Fig. 2, to put a slowly maturing formalism for the composition of such modules to a practical test. We adopt the template-anchor\(^2\) framework [9] to represent this machine’s 4DOF steady sagittal plane running as the hierarchical composition of the low DOF constituents depicted in Fig. 1. At the leaves of this hierarchy tree, we introduce four different 1DOF templates that emerge from the decades old bioinspired running literature [3], [10],

\(^1\)In some robotics settings these disadvantages of the exact or local linearized control paradigm can be effectively remedied by recourse to parameter adaptation [5], but in our experience, such methods are too “laggy” to work in this hybrid dynamics domain with its intrinsically abrupt and rapidly switching characteristics.

\(^2\) The template-anchor relation as exemplified in various physical [4], [7] and numerical [8] studies associates a pair of smooth vector fields, \(f^1, f^A\) on a pair of smooth spaces, \(\mathcal{T} \subset \mathcal{A}\) via the condition that \(\mathcal{T}\) is an attracting invariant submanifold of the anchor field, \(f^A\), whose restriction dynamics is conjugate to that of the template field, \(f^1 \sim f^A|_\mathcal{T}\) (where \(\sim\) denotes equivalence up to smooth change of coordinates). In this paper, we are dealing with hybrid fields and flows for which the extended definition and its verification is a bit more intricate. Thus exceeding the scope and length constraints of the present paper, we will treat the hybrid template-anchor relation as an intuitive notion here.
joined by a new arrival from recent work on bioinspired tails [11], [12]. We apply the four decoupled 1DOF control laws associated with these isolated “leaf” templates directly to the (highly dynamically coupled) physical platform and demonstrate empirically steady sagittal plane running (a circular boom) whose body motions reveal, when viewed in the appropriate coordinates, Fig. 7, striking similarity to the corresponding isolated 1DOF constituents. We show (up to a still unproven technical conjecture) that the appropriate two pairs of these four 1DOF leaf templates are formally anchored by the two “interior” 2DOF templates depicted in Fig. 1, in the sense that the 1DOF systems define attracting invariant submanifolds of the 2DOF systems that exhibit conjugate restriction dynamics. We conjecture, as well, that the two interior nodes (the 2DOF templates) of the figure are in turn formally anchored by a physically realistic dynamical model of the closed loop Penn Jerboa in the sagittal plane. The data of Fig. 7 support this hypothesis, but we have not yet succeeded in completing the proof beyond the embedding and invariance properties.

Notwithstanding the specifics of our compositional approach to its control, we believe that the new physical platform is itself of independent interest by virtue of its added appendage (the “tail”), opening up a multiplicity of diverse uses for both of its two revolute actuators. Note again, however, this diversity of uses cannot be achieved without some recourse to behavioral modularity. In that light, we are particularly attracted by these simple low-DOF template controllers. In our experience, such constructions have the hope of succeeding in unstructured outdoor settings, since they build on the relatively robust template dynamics.

A. Relation to Prior Literature

This “compositional” method of controller synthesis was pioneered empirically by Raibert [13] for planar and 3D hopping machines, and we develop our planar hopping behavior by building up from those ideas. Our physical platform (Fig. 1 center) forgoes Raibert’s prismatic shank actuator, and instead places that actuator in an inertial platform (Fig. 1 center) forgoes Raibert’s prismatic shank behavior by building up from those ideas. Our physical hopping machines, and we develop our planar hopping approach to its control, we believe that the new physical platform is itself of independent interest by virtue of its added appendage (the “tail”), opening up a multiplicity of diverse uses for both of its two revolute actuators. Note again, however, this diversity of uses cannot be achieved without some recourse to behavioral modularity. In that light, we are particularly attracted by these simple low-DOF template controllers. In our experience, such constructions have the hope of succeeding in unstructured outdoor settings, since they build on the relatively robust template dynamics.

in a quasistatic pentapedal gait [17]. In our implementation, the tail contributes the reorientation function in flight, and the energetic “pump” function in stance (albeit in a dynamic fashion). We are not aware of prior robotic locomotion work wherein a tail is used to help power the stance phase.

B. Contributions of the Paper

This paper contributes both to the theory and practice of dynamical legged locomotion.

The principal theoretical contributions are: (i) a new (slightly simplified) further abstraction (§III-C) of the long-standing SLIP running model [3] as a formal cross-product of previously proposed vertical [18] and fore-aft [19] templates; (ii) a stability proof (modulo a restrictive assumption 3) of

The empirical contributions of the paper are: (i) design and implementation of a working tailed biped platform, the Penn Jerboa [20] (Fig. 2); (ii) physical demonstration of the (provably correct—Proposition 1) oscillatory spring-energization scheme for vertical hopping; and (iii) experimental evidence supporting the hypothesis that our final parallel composition of the four isolated controllers does indeed anchor the corresponding templates in the Jerboa body (Fig. 7).

II. PRELIMINARIES: ORGANIZATION AND NOTATION

Table I contains a list of important symbols in this paper, including a set of symbols for describing hybrid dynamical systems. We adopt the modeling paradigm from Definition 1 in [21], representing a hybrid dynamical system by the tuple \((D, f, r)\) as defined in Table I. We only consider two hybrid modes in this paper: ballistic flight, and a stance phase arising from a sticking contact at the “toe”.

Superscripts on each of these symbols denote the hybrid template that it is a part of, e.g. \(*v*\) for controlled vertical hopping (§III-A). The layout of the paper roughly reflects the template-anchor hierarchy depicted in Fig. 1. Namely, there are two intermediate 2DOF templates—the SLIP, \(s\), and the inertial reorientation, \(a\)—that comprise the tailed monopod, \(tm = \{s, a\}\). They, in turn, are comprised of the vertical, \(v\), and fore-aft, \(fa\), 1DOF templates, \(s = \{v, fa\}\), and respectively, the shape, \(sh\), and pitch, \(p\), 1DOF templates, \(a = \{sh, p\}\). We endow the 1DOF templates at the lowest level with an exemplar plant, with respect to which we will develop controllers for the four template plants, in isolation.

Sections III-IV present the 2DOF \(s, a\) templates that are directly anchored in the robot body (§V), and within them contain descriptions of the subtemplates (e.g. §III-A, III-B)—as simple exemplar 1DOF anchoring bodies and corresponding control laws—that comprise in isolation the constituent desired limiting behaviors that we seek to embody simultaneously in our physical system. Each of the template controllers in this suite is necessarily simple by dint of its origin as a feedback law for a highly abstract 1DOF task exemplar. We hypothesize that this combination of algorithmic simplicity and task specialization may lend robustness in the empirical setting since control policies are not sensitive to, and certainly avoid cancellation of, forces arising from dynamical coupling in the anchoring body.

We emphasize that these coupling-naïve feedback laws (summarized in Table II) are simply “played back” (modulo hopping (§III-C)) of a decoupled control law, \(u = g^*(x_1) \times g^*(x_2)\), taken directly from (3), (8), respectively.

\(^3\)By this term we mean the application to the (coupled) plant \(p^2(x, u)\) (§III-C) of a decoupled control law, \(u = g^*(x_1) \times g^*(x_2)\), taken directly from (3), (8), respectively.

propositions in this paper that nevertheless the stability of the templates and subtemplates persists through composition for the distal segments of the tree (Fig. 1)—SLIP as a composition of vertical hopping and fore-aft speed control, and attitude stabilization as a composition of inertial reorientation and Raibert’s pitch control. We provide some preliminary suggestions about the composition of SLIP (\(s\)) with attitude (\(a\)) compartments (center of Fig. 1), but a full analysis is left to future work. However, we offer empirical data in §VI showing how this idea has resulted in promising qualitative behavior on the Jerboa robot (Fig. 7, video attachment).

**Note:** Due to space constraints, we have moved the proofs as well as additional experimental results to a companion technical report [20].

III. THE (2DOF) SLIP TEMPLATE

A. Controlled Vertical Hopping (1DOF)

For a successful hopping behavior, energy must be periodically injected into the robot body to compensate for losses. We simplify the analysis here to a 1DOF vertically-constrained point-mass which can alternate between stance phase (during which the actuator has affordance) and a ballistic (passive) flight phase. It has been shown in the past empirically [13] and analytically [22] that an impulse at the bottom of stance can produce a stable limit cycle, in the presence of a spring for energy storage. In this paper, we consider a different strategy of an actuator forcing the damped spring by applying forces in a phase-locked manner. This choice of input representative is made with an eye toward using a tail actuator exerting inertial reaction forces on the spring (this model is formally instantiated §V). Intuitively, this can be thought of as negative damping [18] (effectively cancelling losses by physical damping).

Throughout this paper, we make the following assumption inspired by [13]:

**Assumption 1** (Stance duration). The duration of stance, \(T_s\), is approximately constant.

This essentially asserts that the damping losses or actuator forces are relatively small compared to the spring-mass dynamics (in their effect on the liftoff condition).

We build upon the “linear spring” analysis in [22] for our vertical hopping exemplar body and closed-loop template. For a spring-mass-damper system with spring deflection \(\chi\), damping coefficient \(\beta\) and natural frequency \(\omega\)

\[
\ddot{\chi} + 2\omega\beta\dot{\chi} + \omega^2\chi = \tau.
\]

With the change of coordinates \(x_1 := \chi, x_2 := \dot{\chi}/\omega, \dot{x} = p^s_1(x, \tau) := -\omega J x + e^T_2(-2\beta\omega x_2 + \tau/\omega), \) and the hybrid reset events occur at \(x_1 = 0\) (corresponding physically to the touchdown and liftoff events at \(\chi = 0\)).

1) Oscillatory Spring Energization: We choose the physically motivated control strategy

\[
\tau := \frac{k_2 x_2}{|x_1|^T x_2} \approx k_2 \cos \angle x, \quad (3)
\]
Proposition 1 (Oscillatory energization stability). The vertical hopping template (4) has a unique attracting periodic orbit. 

Proof. Included in [20].

As a corollary to Proposition 1, we know $F^\gamma_1$ (the vertical stance map, cf. [20]) has an asymptotically stable fixed point, $\chi^\ast$, and $-1 < DF^\gamma_1|_{\chi^\ast} < 1$. 

Ballistic flight simply reverses the velocity, 

$$F^\gamma_2(\hat{\chi}) := -\hat{\chi}. \tag{5}$$

Note that by symmetry ($f^\gamma_1$, and consequently $F^\gamma_1$ are odd), $F^\gamma_1 \circ F^\gamma_1 = F^\gamma_2 \circ F^\gamma_1 \circ F^\gamma_2$, i.e. the stability properties of the hybrid system are the same as that of the stance map as analyzed in Proposition 1. Define

$$\kappa = h_\kappa(\hat{\chi}) := -\frac{F^\gamma_1(\hat{\chi})}{\hat{\chi}}, \tag{6}$$

the effective coefficient of restitution through stance, or the so-called "velocity gain" during SLIP stance [19]. Note that there is a unique fixed point, $\kappa^\ast = 1$, in these coordinates, which is necessary and sufficient for the smooth invertibility of $h_\kappa$, as can be seen by direct computation of its derivative. 

Conjugating the touchdown velocity return map via this diffeomorphism, we can define a return map for $\kappa$, $F^\kappa$,

$$F^\kappa(\kappa) := h_\kappa \circ F^\gamma_2 \circ F^\gamma_1 \circ h_\kappa^{-1}(\kappa) = h_\kappa(h_\kappa h_\kappa^{-1}(\kappa)). \tag{7}$$

Proposition 2 (Vertical stability). The velocity gain return map, $F^\kappa$, has an asymptotically stable fixed point, $\kappa^\ast := 1$, and $DF^\kappa|_{\kappa=1} = -DF^\gamma_1|_{\chi^\ast}$. 

Proof. Included in [20].

B. Controlled Fore-Aft Speed (1DOF)

Running and walking systems of a large variety from the sagittal or frontal plane resemble inverted pendula during stance [3], usually controlled by stepping strategies. It has been shown that a fixed touchdown angle can admit a reasonable basin of stability around an emergent attracting steady-state velocity in SLIP [23]. The capture point [24] and zero moment point [25] methods use a quasistatic heuristic which is related to these ideas, but are not explicitly designed to servo to desired nonzero speeds. We attempt here to place the empirical success of [13] in the context of a model where its stability properties can be analyzed.

1) The Raibert Stepping Controller: In his classical empirical study, Raibert [13] inspired decades of subsequent experimentation and analysis by offering the following observations\(^4\) about the pendular stance phase in his running machine travelling at forward speed, $\dot{x}$, and stepping with a touchdown angle $\beta(\dot{x})$ (as in Fig. 4):

Assumption 2 (Raibert observations), (i) For each speed, $\dot{x}$, there is a neutral\(^5\) touchdown angle, $\beta^\ast(\dot{x})$ (ii) this neutral angle is monotonic with speed, $D_x \beta^\ast > 0$, and (iii) deviations from touchdown angle cause negative acceleration, i.e. $D_\beta(\dot{x}^\ast - \dot{x})|_{\beta=\beta^\ast} < 0$. 

Proposition 3 (Raibert stepping controller). Under assumptions 2(i-iii), the Raibert stepping controller,

$$\beta : \dot{x} \mapsto \beta^\ast(\dot{x}) + k_p(\dot{x} - \dot{x}^\ast) \tag{8}$$

stabilizes the forward speed to $\dot{x}^\ast$. 

Proof. Included in [20].

2) Modified BHop as a Fore-Aft Model: Building on existing SLIP literature [26], we make the following assumptions about pendular stance:

Assumption 3 (Pendular stance). During stance, (i) the effects of gravity are negligible\(^6\) compared to spring potential / damping forces, (ii) radial deflections are negligible, (iii) time of stance is constant, and (iv) the angle swept by the leg admits a small-angle approximation.

Schwind [26] approximated that angular momentum about the toe is constant during stance, but we simplify further with the second assumption, and conclude that the angular velocity is roughly constant during stance. We adopt the third approximation from Raibert [13], and the last approximation is made for the ensuing analytical simplifications in §VI-B, but we find empirically (§VI) that it is not critical in practice.

\(^4\)These conditions are not a direct result of SLIP’s nonlinear dynamics, but are applicable to regime of interest.

\(^5\)In this context, "neutral" means $\dot{x}^\ast = \dot{x}$, where $\dot{x}^\ast$ refers to the fore-aft speed at the subsequent touchdown event.

\(^6\)We suspect that the less restrictive Geyer approximation [27] is sufficient, but leave this generalization to future work.
of SLIP) is taken to be a fixed parameter at this stage, the following return map acting on touchdown velocity in the MBHop model for a range of fore-aft speed $v$.

**Proposition 4** (Fore-aft stability). MBHop with the Raibert controller presents a stable touchdown return map.

*Proof.* Included in [20].

**C. SLIP as a Parallel Composition**

In order to anchor our 1DOF templates in the classical SLIP model (2DOF point mass with 2DOF springy leg), we simply “play back” our devised control schemes (Sections III-A and III-B). In the following subsections, we check that the closed-loop executions in the higher-DOF body still resemble a cross-product of our template behaviors. For instance, prior literature has observed a decomposition of SLIP dynamics into radial and tangential components, but to

$$F^v_v(v, \kappa) = \begin{bmatrix} 1 & -1 \end{bmatrix} R(-\gamma + \beta) \begin{bmatrix} 1 & -\kappa \end{bmatrix} R(-\beta) v,$$

where $\kappa$ (explicitly, the interaction from the radial component of SLIP) is taken to be a fixed parameter at this stage, $\gamma(v_1) \approx \frac{v_1 T_m}{m_i}$ is the angle swept by the leg over the course of stance and $\beta(v_1)$ is the leg touchdown angle (§ III-B.1). This model is only a slight modification of BHop [19].

This analytically tractable model (i) allows us to “separate” the radial dynamics (encapsulated in $\kappa$) from the contributions of the fore-aft model itself, (ii) captures the exchange of vertical and horizontal energy through stepping, and (iii) matches the empirically observed Raibert conditions (Fig. 5) as well as empirical data (Fig. 7), suggesting it is physically applicable and not just an analytical convenience.

For now we restrict our attention to $\kappa = 1$, and generalize to include the radial dynamics in § III. With this restriction,

$$F^v_s(v) := F^v(v, 1) = R(\gamma - 2\beta) v,$$

while we choose to parameterize the return map as a function of $v \in \mathbb{R}^2$, it is really a 1D map:

**Proposition 4** (Fore-aft stability). MBHop with the Raibert controller presents a stable touchdown return map.

*Proof.* Included in [20].

**Proposition 5** (Stability of SLIP as a composition). For (i) stable vertical hopping with $-1 + \varepsilon_r < -DF^v_\kappa |_{\kappa} < 1 - \varepsilon_r$, (ii) sufficiently small $k_p$ in the Raibert controller, parallel composition of the radial and fore-aft templates results in a locally stable 2D return map, $F^v$.
completely actuated in, one and then other, of the alternating mean that both of the two decoupled 1DOF systems are (albeit in alternating stages of the hybrid execution).

In (14) we have now respectively, and \( p \) in independent energization in the physical system). In (14) we have now spectively, and \( \delta \) is an unmodeled disturbance term (explicitly added here with an eye toward the use of tail for spring energization in the physical system). In (14) we have now represented HIR as two independent subsystems on which two identical 1DOF templates will be anchored in parallel (albeit in alternating stages of the hybrid execution).

Taking advantage of the direct affordance (by which we mean that both of the two decoupled 1DOF systems are completely actuated in, one and then other, of the alternating modes of their hybrid dynamics), we employ a graph-error controller [30] as a type of reduction. Since our reference first-order dynamics are just \( \dot{a} = -ka_1 \), the independent closed-loop 1DOF subtemplate vector fields, \( f^p : T_1 \rightarrow T \dot{a}_1 \) and \( f^{\delta} : T_2 \rightarrow T \dot{a}_2 \), are defined as

\[
\dot{a}_i = -k_g (a_i + ka_i) = -k_g a_i - k_g \dot{a}_i, \tag{15}
\]

where the gain \( k_g \) is understood to be high enough to make the transients of the anchoring dynamics irrelevant.

A. Hybrid Dynamical Model of HIR

Since the isolated model does not have any intrinsic physical mechanism for transitioning between modes, we add an exogenous clock signal, \( \psi_a \in S^1 \) such that \( \psi_a \in [0, \pi] \) represents stance, and the complement represents flight. In this paper we sidestep the issue of phase-synchronization for the various compartments, but simply use \( \psi_a \) to ensure our gains our tuned properly for the timescales of the coupled system (Proposition 8).

Define \( \mathcal{D} = TS^2 \times \{(0, \pi] \cup (\pi, 2\pi]\} \). Now the closed-loop template dynamics, \( f^a : T S^2 \times S^1 \rightarrow T(TS^2 \times S^1) \) can be specified as

\[
f_1^a([T_{\psi_a}]) = \begin{bmatrix} -k_g k & 0 & 0 & 0 \\ 0 & -k_g k & 0 & 0 \\ 0 & 0 & -k_g k & 0 \\ 0 & 0 & 0 & -k_g k \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{bmatrix},
\]

\[
f_2^a([T_{\psi_a}]) = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix},
\]

the guards sets are \( \partial \mathcal{D} = TS^2 \times \{(\pi] \cup [2\pi]\} \) and the reset maps \( r^a = \text{id} \) simply modify the dynamics (14) at \( \psi_a = \pi \) (flight to flight) and \( \psi_a = 0 \) (flight to stance).

B. HIR Stability Analysis

Let us denote \( \bar{\delta}[i] := \int \hat{\delta} dt \), the interval being over the stance phase of stride \( i \). Also, define \( \bar{\delta}_{\text{max}} = \max_i \bar{\delta}[i] \).

Proposition 6 (HIR Stability). Setting

\[
k > \frac{2\omega}{\pi} \log (1 + \bar{\delta}_{\text{max}}/\varepsilon_a)
\]

results in the desired limiting behavior for \( F^a : \|a\| \rightarrow B_{\varepsilon_a}(0) \), a neighborhood of 0 of size \( \varepsilon_a \).

Proof. Included in [20].

V. PHYSICAL SYSTEM: TAILED MONOPED

Our target physical platform is a tailed bipedal robot that we have built [20], which (when planarized) we model as shown in the center of Fig. 1. We were able to formally show template-anchor relations going from 1DOF to 2DOF templates (Propositions 5 and 6), because of the availability of simple models (§III-B.2), or trivial dynamics (§IV). However, as we proceed up the desired hierarchy (Fig. 1), there are no easily accessible tools that let us directly analyze the effects of coupling in the return map. In this section, we only show (Proposition 8) that under a highly restrictive assumption 4 (that essentially makes the tail sweep negligible), the closed-loop tailed monoped return map \( F^\text{tm} \) has an invariant submanifold where it is equal to \( F^a \times F^a \), but we also leave as conjecture that this invariant submanifold is attracting.
A. Modeling for Planar Hopping

Raibert’s planar hopper [13] empirically demonstrated stable hopping using a rigid body with a springy leg, and in this paper we pursue the same idea, but instantiate vertical hopping by coupling the 1-DOF leg-spring excitation controller (physically acting through the tail). In flight, the tail actuator grants us a new affordance that we only\(^{10}\) use here to regulate the added “shape” DOF. Our physical model is shown in Fig. 1 (center). The system has a single massless leg with joints \(\theta = (\theta_1, \theta_2) \in S^2 \times \mathbb{R}_+\), a rigid body \((x, z, \phi_1) \in \mathbb{SE}(2)\), and a point-mass tail with revolute DOF \(\phi_2\), such that the full configuration is \(q := (\theta_1, \theta_2, x, z, \phi_1, \phi_2) \in \mathcal{Q}\). We make the following design-time assumptions:

**Assumption 4.** (i) Leg/tail axes of rotation are coincident at the “hip,” (ii) tail mass is small, i.e. \(m_t \ll m_b\), (iii) center of mass (configuration-independent by the previous assumption) coincides with the hip, and (iv) body, tail have high inertia, i.e. \(i_b, i_t \to \infty\).\(^{11}\)

We derive the equations of motion in [20].

B. “Physical” Decoupling and Anchoring

With the highly restrictive assumption 4 (allowing for infinite tail inertia), the tail motion is essentially negligible. Under these conditions, we show the emergence of the beginnings of a classical anchoring relation [9], via a natural (weak) decoupling of the 6DOF dynamics into “point-mass” and attitude compartments. A more general analysis that is more physically relevant is forthcoming in future work.

**Proposition 7** (Flow-invariant submanifold). Under assumption 4, in each hybrid mode, (i) the submanifold \(\mathcal{U} = \{Tq \in T\mathcal{Q} : T\phi_1 = T\phi_2 = 0\}\) is invariant under the action of the flow generated by \(f^T_i\), and (ii) in each hybrid mode, the closed-loop flow restricted to \(\mathcal{U}\), \(\dot{q} = f^T_i(Tq|_{\mathcal{U}})\) is a cross-product of the template vector fields,

\[
    f^T_i = f^T_i \circ \pi_s \times f^T_i \circ \pi_a, \tag{17}
\]

where \(\pi_s\) and \(\pi_a\) represent projections to the SLIP and attitude components of \(q\) respectively.

**Proof.** Included in [20].

Additionally, the invariant submanifold in the flow leads to an invariant submanifold in the hybrid execution:

**Proposition 8** (Return map-invariant submanifold). The set \(\mathcal{U}\) is invariant under the return map \(F^T_i(Tq|_{\mathcal{U}})\), and restricted to \(\mathcal{U}\), \(F^T_i = F^T_i \circ \pi_s \times F^T_i \circ \pi_a\).

**Proof.** Included in [20].

We leave to future work a proof that \(\mathcal{U}\) is attracting, which is a requirement for demonstration of anchoring [9].

\[^{10}\]We avoid a detailed discussion here, but a revolute tail avoids the morphological specialization of a dedicated prismatic actuator and can be repurposed for other uses such as static standing, reorienting the body in free fall [12], directing reaction forces through ground contact for leaping when used as another “leg” [31], etc.

\[^{11}\]Even though the dynamic task here is quite different from free-fall, in the language of [12] this is saying that the tail should be light but effective.

VI. Experimental Results

We perform the experiments on the Penn Jerboa: a new tailed bipedal robot platform (Fig. 2) with a pair of compliant hip-actuated legs (in parallel for sagittal plane behaviors), and a 2DOF revolute point-mass tail [12] driven differentially by two motors through a five-bar mechanism (locked in the sagittal plane for the behaviors in this paper). We include a detailed design report as well as additional experimental results including the effect of varying tail mass, and empirical validation of our pitch/shape decomposition of §IV in [20].

By physically constraining some of the DOFs, we test our hierarchical composition (Fig. 1) at as many “nodes” of the composition tree as possible. Note that it is infeasible to isolate the fore-aft or the closed-loop pitch correction templates in a physical setting. The results are summarized in Fig. 7. Five strides are averaged within each category, and aligned with ground truth knowledge of the touchdown event. We observe that

i) there is a vertical limit cycle that retains its rough profile and magnitude through three anchoring bodies,

ii) the hip angle roughly satisfies \(\dot{\theta}_1 = 0\) in stance and the stance duration is roughly constant (corroborating assumptions 3.ii-iii, and our MBHop model (9)),

iii) the shape coordinate is destabilized in stance and stabilized in flight, and the pitch-deflections are small in magnitude over the stride, and in agreement with (16).

Qualitatively, the “tailed point-mass hopper” configuration attained stable forward hopping at controlled speeds upwards of 20 strides, only limited by space. The fully unlocked system has so far hopped for about 10 strides at multiple instances before failing due to accumulated error causing large deviations from the limit cycle. We believe the prime reason for this is that the CoM is significantly aft of the hip (violating assumption 4.i). We attempted to compensate for this effect with a counterbalance visible in Fig. 2, but an unacceptably large weight would have been required to completely correct the problem.

In the video attachment, we include clips of the robot
hopping along a boom, with varying degrees of physical constraint corresponding to the “bodies” of Fig. 7 (annotated in the video). The controller implemented on the hardware is agnostic of the physical constraint, and takes the decoupled form of a cross-product of the rows of Table II.

VII. DISCUSSION AND CONCLUSION

Raibert’s hopper [13] made significant empirical advances in the field of robotics, but to our knowledge, no previous account in the literature has provided any formal conditions under which such simple and decoupled control strategies will work. In this paper, we apply simple decoupled controllers using similar ideas (including the exact same forefront (8) and pitch (16) controllers), but with a new vertical hopping scheme (§III-A) and a new tail appendage to enable it. Moreover, we construct abstract models (that appear to, nevertheless, be representative of empirical data) that enable us to present analyses of stability for each of these subsystems, and make steps towards a local proof of stability for the tilted hopper (a subject of future work by the authors).

The first focus of future work is a complete analysis of stability of tail-energized hopping on the Jerboa, and development of formal tools for design and verification of parallel composition. Second, our analysis in this paper is very specifically targeted to the tilted hopper (including the hand-designed hierarchy in Fig. 1), but in future work we plan to generalize these ideas to other tasks as well as platforms. As explained in §II, we focus on closed-loop templates in this paper, but there is an accompanying interesting problem of assignment of actuator affordances to the control of specific compartments. Lastly, we see in this paper that a sufficient condition for enabling a simple parallel composition is a physical decoupling (§V-B) through the design (summarized in assumption 4) and natural dynamics of the system. In the future we wish to leverage recent advances in self-manipulation [28] to enable a direct analysis of the system dynamics, perhaps even enabling tools for designing machines based on a desired composition hierarchy (Fig. 1).
