A hybrid dynamical extension of averaging and its application to the analysis of legged gait stability

Abstract
We extend a smooth dynamical systems averaging technique to a class of hybrid systems with a limit cycle that is particularly relevant to the synthesis of stable legged gaits. After introducing a definition of hybrid averageability sufficient to recover the classical result, we illustrate its applicability by analysis of first a one-legged and then a two-legged hopping model. These abstract systems prepare the ground for the analysis of a significantly more complicated two legged model—a new template for quadrupedal running to be analyzed and implemented on a physical robot in a companion paper. We conclude with some rather more speculative remarks concerning the prospects for further extension and generalization of these ideas.

A hybrid dynamical extension of averaging and its application to the analysis of legged gait stability

Avik De¹, Samuel A. Burden² and Daniel E. Koditschek¹

Abstract
We extend a smooth dynamical systems averaging technique to a class of hybrid systems with a limit cycle that is particularly relevant to the synthesis of stable legged gaits. After introducing a definition of hybrid averageability sufficient to recover the classical result, we illustrate its applicability by analysis of first a one-legged and then a two-legged hopping model. These abstract systems prepare the ground for the analysis of a significantly more complicated two legged model—a new template for quadrupedal running to be analyzed and implemented on a physical robot in a companion paper. We conclude with some rather more speculative remarks concerning the prospects for further extension and generalization of these ideas.

1 Introduction
The emergence of physically motivated and mathematically tractable hybrid models Johnson et al. (2016); Burden et al. (2016, 2015) offers the prospect of extending classical ideas and techniques of dynamical systems theory for application to new settings arising from the repeated making and breaking of contacts endemic to robotic mobility and manipulation. In this paper we work at the intersection of a class of tractable hybrid legged locomotion models Johnson et al. (2016) with a class of well–behaved hybrid limit cycle models Burden et al. (2015) to generalize an initial result De and Koditschek (2015a) on the stability of “averageable” hybrid oscillators. Specifically, we extend a classical smooth dynamical averaging technique to a class of hybrid systems with a limit cycle that is particularly relevant to the synthesis of stable gaits.

We also present three applications of the new averaging result to prove stability of hybrid limit cycles, first for an isolated vertically hopping leg, then for two physically decoupled (but informationally coupled) vertically hopping legs exhibiting in-phase (“pronking”) and anti-phase (“bounding”) limiting phase offsets. In a companion paper we use the same result to prove stability in a mechanically–coupled pair of vertical hoppers De and Koditschek (2016), a model which provides remarkable insight into preflexive and feedback stabilization of these gaits on a physical quadruped machine.

1.1 Relation to prior literature
Classical averaging (Guckenheimer and Holmes 1990, Ch. 4.1) yields a method of approximating (with error bounds) solutions of the $T$-periodic vector field (1) using the averaged vector field (3). As in the classical case, our new hybrid results guarantee equivalence in stability type to a simpler approximant (named the averaged system) of the system of interest. Specifically, we show that if the return map of the averaged system has a hyperbolic periodic orbit, then so does the original system, and additionally the linearizations of the return maps are $\epsilon^2$-close (and thus share the same eigenvalues and eigenvectors to $O(\epsilon)$).

This paper is also related to previous stability analyses of hybrid oscillators appearing in locomotion for a single vertical hopper Koditschek and Buehler (1991), as well as informationally-coupled, physically-decoupled vertical hoppers Klavins et al. (2000); Klavins and Koditschek (2002). Application of the hybrid averaging result in these instances yields a greater analytical simplification than has been possible before. In fact, we show in our analysis...

that the nonlinear stance dynamics in our vertical hopper (Sec. 4.1) can be reduced to an “averaged” continuous dynamics that appears as a phase-independent proportional controller on the energy (43). While single-vertical-hopper stability results have been obtained before without averaging (e.g. Koditschek and Buehler (1991)), the more complex latter instance (informationally-coupled vertical hoppers) has heretofore only been analyzed in the context of a simplified, integrable Hamiltonian (i.e., lossless) stance model (Klavins and Koditschek 2002, eqn. (20)). Integrable stance dynamics allowed for a discrete return map control strategy (Klavins and Koditschek 2002, eqn. (26)), but cannot be extended to more general (e.g., 2DoF or greater) non-integrable dynamical templates such as the so-called Spring-Loaded Inverted Pendulum (SLIP) Sarani et al. (1998). Hybrid averaging allows us to analyze with relative ease the general (non-Hamiltonian) paired vertical hopper plant model obviating the need to integrate the time-varying flow and, rather, requiring only examination of its reduced-dimensional, simplified, averaged approximant (Sec. 4). Formal stability analyses of such non-integrable 2DoF models has not been achieved thus far in the literature, leading past researchers to resort to numerical methods Poulakakis (2006); Shahbazi and Lopes (2016). Further work is currently underway to use hybrid averaging in conjunction with observations on time-reversal symmetry Altendorfer et al. (2004); Razavi et al. (2016) to provide stability analyses of still higher DoF coupled systems including the SLIP template Full and Koditschek (1999) and its anchoring physical models that encodes fore-aft motion as well as vertical travel.

### 1.2 Contributions and organization

After proving the formal result, we first apply it to a simple one degree of freedom vertical hopper to provide a lightweight illustration of how its hypotheses—inherit

Sec. 4 illustrates the utility of this result from Sec. 2 to
the stability analysis of the models introduced in Sec. 3
by application of Thm. 2 or 3. We offer accompanying
simulation results in Sec. 5 suggesting the physical
relevance of this theory that will be demonstrated in the
companion paper De and Koditschek (2016).

Sec. 6 concludes with a discussion of the limitations
in the presently required conditions and some more
speculative remarks on their relaxation as well as extensions
to facilitate applications to higher dimensional problems.

2 Hybrid averaging

2.1 Classical averaging (background)

Following Guckenheimer and Holmes (1990), consider a
time-varying system

$$\dot{x} = \varepsilon f(x, t, \varepsilon); \quad x \in \mathbb{U} \subset \mathbb{R}^n \quad 0 < \varepsilon \ll 1. \quad (1)$$

The averaged system is defined as

$$\dot{y} = \frac{1}{T} \int_0^T f(y, t, \varepsilon) dt =: \varepsilon \overline{f}(y). \quad (2)$$

Note that $y$ is used instead of $x$ to make clear that these
vector fields act on different coordinates. We describe the
necessary coordinate change below.

**Theorem 1.** Smooth Averaging Theorem Guckenheimer
and Holmes (1990). There exists a $C'\!$ change of
coordinates $x = y + \varepsilon w(y, t, \varepsilon)$ under which (1) becomes

$$\dot{y} = \varepsilon \overline{f}(y) + \varepsilon^2 f_1(y, t, \varepsilon). \quad (3)$$

Moreover,

(i) If $x(t)$ and $y(t)$ are solutions of (1) and (2) with
initial conditions $x(0), y(0)$ respectively, and $|x(0) -
y(0)| = O(\varepsilon)$, then $|x(t) - y(t)| = O(\varepsilon)$ on a time
scale $t \sim 1/\varepsilon$.

(ii) If $f$ is periodic with period $T$, and if $p_0$ is a
hyperbolic equilibrium of (2) then there exists $\varepsilon_0 > 0$
such that, for all $0 < \varepsilon \leq \varepsilon_0$, (1) possesses a unique
hyperbolic periodic orbit $y_\varepsilon(t) = p_0 + O(\varepsilon)$, of the
same stability type as $p_0$.

**Remark 1.** The statement (i) does not depend on the
periodicity assumption made in Guckenheimer and Holmes
(1990); but (ii) does. Further, we emphasize that we don’t
directly compare the behaviors of (1) and (2); instead we
change coordinates for the original vector field from $x$ to $y$,
and then compare the behavior of the original system in the
new coordinates, (3), to the “model averaged system” (2).

Below, we replicate the proof of Thm. 1 from
Guckenheimer and Holmes (1990), so that unfamiliar
readers have an accessible reference for this result, which
our novel contributions depend heavily on.

**Proof (from Guckenheimer and Holmes (1990)).** First,
we compute the change of coordinates explicitly. Let

$$f(x, t, \varepsilon) = \overline{f}(x) + \tilde{f}(x, t, \varepsilon) \quad (4)$$

be split into its mean, $\overline{f}$, and oscillating, $\tilde{f}$, parts. Let

$$x = h(y) := y + \varepsilon w(y, t, \varepsilon), \quad (5)$$

without yet choosing $w$. Differentiating the equation above
and using (1) and (4), we have

$$(I + \varepsilon D_y w) \dot{y} = \dot{x} - \varepsilon \frac{\partial w}{\partial t}$$

or (expanding in powers of $\varepsilon$, and choosing $w$ such that
$\varepsilon \frac{\partial w}{\partial y} \preceq \tilde{f}$, $\overline{f}$, parts. Let

$$\dot{y} = \varepsilon (I + \varepsilon D_y w)^{-1} \left[ \overline{f}(y) + \varepsilon D_y \overline{f} \cdot w(y, t, 0) +
\tilde{f}(y, t, 0) + \varepsilon \frac{\partial \overline{f}}{\partial y}(y, t, 0) + \varepsilon^2 \frac{\partial \overline{f}}{\partial \varepsilon}(y, t, 0) \right] \quad + O(\varepsilon^3)$$

as required by (3).

We use a version of Gronwall’s Lemma (see Gucken-
heimer and Holmes (1990) for details) to compare solutions
of (2) and (3). If $y(t)$ and $y_\varepsilon(t)$ are their respective
solutions, the Lemma says that if $|y(0) - y_\varepsilon(0)| = O(\varepsilon)$, then
$|y_\varepsilon(t) - y(t)| = O(\varepsilon)$ for $t \in [0, \frac{1}{\varepsilon}]$. Using the coordinate
change (5), we know

$$|x(t) - y_\varepsilon(t)| = \varepsilon w(y_\varepsilon(t), t, \varepsilon) = O(\varepsilon),$$

and using the triangle inequality,

$$|x(t) - y(t)| \leq |x(t) - y_\varepsilon(t)| + |y_\varepsilon(t) - y(t)| = O(\varepsilon),$$

and we obtain the desired result (i).

To prove (ii), we again follow the proof strategy
of Guckenheimer and Holmes (1990), but provide
significantly more detail as well as correct some typos in
the original. We also enumerate the steps in order to better
reference them in the following text.
(a) We consider the Poincare maps $P_0$ and $P_\varepsilon$ associated with (2) and (3). Rewriting these latter systems as

\[
\begin{align*}
\dot{y} &= \varepsilon \mathcal{T}(y), & \dot{\theta} &= 1, \quad (7) \\
\dot{y} &= \varepsilon \mathcal{F}(y) + \varepsilon^2 f_1(y, \theta, \varepsilon), & \dot{\theta} &= 1, \quad (8)
\end{align*}
\]

where $(y, \theta) \in \mathbb{R}^n \times S^1$, and $S^1 = \mathbb{R}/T$ is a circle of length $T$. We define a global cross-section $\Sigma := \{(y, \theta) : \theta = 0\}$, and the first return or time $T$ Poincare maps $P_0 : \Sigma \rightarrow \Sigma$, $P_\varepsilon : \Sigma \rightarrow \Sigma$ are then defined for (7), (8) as the flow maps associated with a time-$T$ flow of each of the time-varying dynamics with initial condition $t = 0$, where $\Sigma \subseteq \Sigma$ is some open set.

(b) If $p_0$ is a hyperbolic equilibrium of (2), then $\mathcal{T}(p_0) = 0$. Using (Hirsch et al. 1974, pg. 300), the spatial Jacobian of the flow around and equilibrium is that of a linear time-invariant system, and so\(^3\)

\[
DP_0(p_0) = e^{T \mathcal{D} \mathcal{T}(p_0)} = I + \varepsilon T \mathcal{D} \mathcal{F}(p_0) + O(\varepsilon^2), \quad (9)
\]

(c) Note that $P_\varepsilon$ is $\varepsilon$-close\(^4\) to $P_0$ since $T$ is fixed independent of $\varepsilon$, using the result of (i)\(^5\). Next we show that $DP_\varepsilon(p_\varepsilon) = DP_0(p_0) + O(\varepsilon^2)$. For this, consider the time-invariant vector field corresponding to (8),

\[
\begin{bmatrix}
\dot{y} \\
\dot{\theta}
\end{bmatrix} = \begin{bmatrix}
\varepsilon \mathcal{F}(y) + \varepsilon^2 f_1(y, \theta, \varepsilon) \\
1
\end{bmatrix}.
\]

and define its time-$t$ flow from initial condition $(y, \theta)$ as $\Phi_\varepsilon(y, \theta, t)$, versus the corresponding flow $\Phi_0(y, \theta, t)$ for (7). Note that, by definition, $P_\varepsilon(p) := \pi_y \Phi_\varepsilon(p, 0, T)$, where $\pi_y$ is the projection to the $y$-coordinates. Following (Hirsch et al. 1974, pg. 300) to compute the spatial derivative of the flow, we get the linear time-varying system where $A(t) := \mathcal{D} \Phi_\varepsilon(y(t), 0, t)$,

\[
\dot{A}(t) = \begin{bmatrix}
\varepsilon \mathcal{D} \mathcal{F} + \varepsilon^2 \mathcal{D}_y f_1 & \varepsilon^2 \mathcal{D}_\theta f_1 \\
0 & 1
\end{bmatrix} A(t).
\]

We can solve this linear time-varying system using the Peano-Baker series. Since we are only interested in the top left block, we can compute it at $p_0$,

\[
\begin{align*}
DP_\varepsilon(p_\varepsilon) &= I + \varepsilon \int_0^T \mathcal{D} \mathcal{F}(p_\varepsilon) d\theta + O(\varepsilon^2) \\
&= I + \varepsilon \int_0^T \left[ \varepsilon \mathcal{D} \mathcal{F}(p_\varepsilon) - \varepsilon \mathcal{D} \mathcal{F}(p_0) \right] d\theta + O(\varepsilon^2) \\
&= I + \varepsilon T \mathcal{D} \mathcal{F}(p_0) + O(\varepsilon^2) \\
&= DP_0(p_0) + \varepsilon \int_0^T \left[ \mathcal{D} \mathcal{F}(p_\varepsilon) - \mathcal{D} \mathcal{F}(p_0) \right] d\theta + O(\varepsilon^2) \\
&= DP_0(p_0) + O(\varepsilon^2),
\end{align*}
\]

where we used the fact that $\mathcal{D} \Phi_0(p_0, \theta, t) = \mathcal{D} \Phi_0(p_0, 0, T) = 0$ for step $\ast$. From (i), for $\theta \in [0, T]$ we know that $\| \mathcal{D} \Phi_\varepsilon(p_\varepsilon, \theta, t) - \mathcal{D} \Phi_\varepsilon(p_0, \theta, t) \| = O(\varepsilon) \Rightarrow \mathcal{D} \Phi_\varepsilon(p_\varepsilon, \theta, t) = \mathcal{D} \Phi_0(p_0, \theta, t) + O(\varepsilon)$. Additionally, $\mathcal{D} \mathcal{T}$ is Lipschitz continuous and so $\mathcal{D} \mathcal{T}(\Phi_\varepsilon(p_\varepsilon, \theta, t)) = \mathcal{D} \mathcal{T}(\Phi_0(p_0, \theta, t)) + O(\varepsilon)$. Using this in the block equation above, we have $DP_\varepsilon(p_\varepsilon) = DP_0(p_0) + O(\varepsilon^2)$.

(d) Consider the function $\xi(p, \varepsilon) := \frac{1}{\varepsilon} \left( P_\varepsilon(p) - p \right)$\(^6\) such that $D_\varepsilon \xi = \frac{1}{\varepsilon} (e^{\varepsilon T \mathcal{D} \mathcal{F}(p)} - I)$, and $\lim_{\varepsilon \to 0} D_\varepsilon \xi = T \mathcal{D} \mathcal{F}(p)$. Note that zeros of $\xi$ correspond to fixed points of $P_\varepsilon$, and that $D_\varepsilon \xi(p_\varepsilon, \varepsilon) = T \mathcal{D} \mathcal{F}(p_0) = 0$. The implicit function theorem implies that the zeros of $D_\varepsilon \xi$ form a smooth curve $(p_\varepsilon, \varepsilon) \in \mathbb{R}^n \times \mathbb{R}$. Thus $p_\varepsilon$ are fixed points of $P_\varepsilon$, and further, $p_\varepsilon = p_0 + O(\varepsilon)$.

(e) Putting together the prior steps, we see that

\[
DP_\varepsilon(p_\varepsilon) = e^{\varepsilon T \mathcal{D} \mathcal{F}(p_\varepsilon)} = \exp\left[ \varepsilon T \mathcal{D} \mathcal{F}(p_0) + O(\varepsilon^2) \right] = \exp\left[ \varepsilon T \mathcal{D} \mathcal{F}(p_0) + O(\varepsilon^2) \right] + O(\varepsilon^2).
\]

or, $DP_\varepsilon(p_\varepsilon) = DP_0(p_0) + O(\varepsilon^2)$.

(f) Due to (d) and (e), the eigenvalues of $DP_\varepsilon(p_\varepsilon)$ are $\varepsilon^2$ close to those of $DP_0(p_0)$. Consequently, the stability properties of $P_\varepsilon$ at its fixed point, $p_\varepsilon$, are the same as that of $P_0$ at its fixed point, $p_0$.

Thus (8) has a periodic orbit $\varepsilon$-close to $p_0$, and via the change of coordinates (5), equation (1) has a similar orbit.

2.2 Switching systems (fixed-interval reset)

The smoothness assumption of Thm. 1 precludes its application to legged locomotion, since the making and
breaking of contacts with the environment is a crucial component of this domain. We begin by introducing (in this subsection) discrete “reset” maps that interrupt the continuous flow of (1) at fixed time intervals, which fall under the umbrella of “switching” systems Van Der Schaft and Schumacher (2000), and in Sec. 2.3 we generalize to a state-dependent event-based reset, which typically arises in legged locomotion Johnson et al. (2016).

2.2.1 Averaging coordinate change Even though not required for the proof of Thm. 1, we will find it useful to delve deeper into the structure of the coordinate change (5). As pointed out in the proof of Thm. 1, w is a solution to the PDE \( \frac{dw}{dt} := \tilde{f}(y,t,0) \). From this we make the following observations:

- \( w \) does not depend on \( \varepsilon \);
- the base value of \( w \) at \( t = 0 \) is not yet constrained, so we are free to choose (as in (Guckenheimer and Holmes 1990, Example 1, Sec. 4.2))

\[
    w(y,0,\varepsilon) \equiv 0 \text{ for all } y, \varepsilon; \tag{10}
\]

- \( h \) in (5) is a good change of coordinates for sufficiently small \( \varepsilon > 0 \), since it is \( \varepsilon \)-close to the identity map;
- since the right-hand side of \( \frac{\partial w}{\partial t} := \tilde{f}(y,t,0) \) does not depend on \( w \), and also since \( y \) is held fixed while taking the partial derivative w.r.t. \( t \), this PDE can be solved by simply integrating over \( t \), i.e.

\[
    w(y,t,\varepsilon) := \int_0^T \tilde{f}(y,\sigma,0)d\sigma \tag{11}
\]

is a solution of (5).

We illustrate in several examples in De (2017) that (11) is indeed a coordinate change from (1) to (3).

**Lemma 1.** Endpoint behavior of averaging coordinate change. At \( t = T \), the coordinate change \( w \) has the properties

(i) \( w(y,T,\varepsilon) = 0 \), and

(ii) \( D_y w(y,T,\varepsilon) = 0 \).

**Proof.** We have

\[
    w(y,T,\varepsilon) \overset{(5)}{=} \int_0^T \tilde{f}(y,\sigma,0)d\sigma \overset{(4)}{=} \int_0^T f(y,\sigma,0)d\sigma - T\overline{f}(y) \overset{(2)}{=} 0
\]

by the definition of \( \overline{f} \). Similarly,

\[
    \begin{align*}
    D_y w(y,T,\varepsilon) & \overset{(5)}{=} \int_0^T D_y \tilde{f}(y,\sigma,0)d\sigma \\
    & \overset{(4)}{=} \int_0^T D_y f(y,\sigma,0)d\sigma - TD_y \overline{f}(y) \\
    & = D_y \left( \int_0^T f(y,\sigma,0)d\sigma - T\overline{f}(y) \right) \overset{(2)}{=} 0,
    \end{align*}
\]

where in the penultimate step, we switched the order of the derivative and the integral.

We remark here that the result of Lemma 1 is unsurprising: the intuitive purpose of \( \tilde{f} \) is to capture the “deviation” between the original vector field \( f \) (1) and \( \overline{f} \) (2), and we should expect (from the definition of the “average” vector field) that the deviation integrates to 0.

2.2.2 Switching systems (constant flow time) Now suppose that instead of a smooth periodic system, we have a switching system with the flow of (1) punctuated by a reset, \( R \) (acting on the original \( x \)-coordinates). We assume for this section that the reset acts after a fixed flow time, \( T \), of (1), and relax this assumption in the next section.

**Theorem 2.** Switching Averaging Theorem. Given the “original” and “averaged” switching systems of the forms

\[
    \begin{align*}
    \dot{x} &= \varepsilon f(x,t,\varepsilon), \quad \dot{\theta} = 1, \quad x(T^+) = R(x(T)), \quad (12) \\
    \dot{y} &= \varepsilon \overline{f}(y), \quad \dot{\theta} = 1, \quad y(T^+) = R(y(T)), \quad (13)
    \end{align*}
\]

where \( R \) is allowed to vary with \( \varepsilon \), \( T^+ \) refers to a limit from the right and \( \theta \) is reset to 0 by the switching event,

(i) the \( C^r \) (for \( r \geq 1 \)) reset \( R \) satisfies (a) \( D_x R(x) = S_0 + \varepsilon S_1(x,\varepsilon) \) (with constant \( S_0 \)), (b) \( S_0 \) is invertible, and its unity eigenvalues have diagonal Jordan blocks (i.e. unity eigenvalues have algebraic multiplicity 1), and

(ii) there is a point \( p_0 \) such that (a) it is an equilibrium of \( \overline{f} \), (b) \( R(p_0) = p_0 \), and (c) the averaged return map is hyperbolic at \( p_0 \).

there exists \( \varepsilon_0 > 0 \) such that, for all \( 0 < \varepsilon \leq \varepsilon_0 \), (12) possesses a unique hyperbolic periodic orbit, of the same stability type as \( p_0 \).

**Proof.** First, we apply the \( C^r \) coordinate change (5). As shown in the proof of Thm. 1(i), \( w \) converts the continuous dynamics in (12) to take the form of (3). Define the reset after the averaging coordinate change (5),

\[
    R_y := h^{-1} \circ R \circ h, \quad (14)
\]
and convert (12) to the switching system
\[
\dot{y} = \varepsilon f(y) + \varepsilon^2 f_1(y, \theta, \varepsilon), \quad \dot{\theta} = 1,
\]
\[
y(T_+) = R_y(y(T)),
\]
where \((y, \theta) \in \mathbb{R}^d \times S^1\), and \(S^1 = \mathbb{R}/T\) is a circle of length \(T\). We know that the continuous flow of (15) can be approximated by (2) after changing coordinates; but we need to check how \(R_y\) and \(R\) are related using (14).

First, note that since \(R_y\) only acts on \(y(T)\), and since the time dynamics in (15) are decoupled, we only ever need compute \(R_y(y(T))\), and \(D_R R_y(y(T))\). From (5) and (14),
\[
R_y(y(T)) = R(x(T)) - \varepsilon w(x(0), 0, \varepsilon)
\]
\[
(10) \quad R(x(T)) = R(y(T)),
\]
where we used Lemma 1 to observe that \(x(T) = y(T) + \varepsilon w(y(T), T, \varepsilon) = y(T)\) for the last equality, and where \(T_+ = 0\) after the reset. Similarly, for the spatial Jacobian, first note that \(D_y w(y, 0, 0) = 0\) from the assertion (10) for each \(y(0)\). Then,
\[
DR_y(y(T)) = DR(x(T))\left[I + \varepsilon D_y w(y(T), T, \varepsilon)\right]
\]
\[
= DR(y(T)),
\]
where we used Lemma 1 for the last step.

The remainder of this proof follows closely the proof of Thm. 1(ii), and we refer to those steps when convenient. Consider the Poincaré maps \(P_0, P_e\), and associated with (13) and (15). Define a section \(\Sigma := \{(y, \theta) : \theta = 0\}\), and the first return or time \(T\) Poincaré maps \(P_0 : \mathcal{U} \to \Sigma\), \(P_e : \mathcal{U} \to \Sigma\) are then defined for (13), (15) as the flow maps associated with a time-\(T\) flow of each of the time-varying dynamics, with initial condition \(t = 0\), composed with their respective resets
\[
P_0 := R \circ Q_0, \quad P_e := R_y \circ Q_e,
\]
where \(\mathcal{U} \subseteq \Sigma\) is some open set, and \(Q_0, Q_e\) are the time-\(T\) flows.

As shown in steps (b)-(e) in the proof of Thm. 1(ii), \(DQ_0(p_0) = \exp[\varepsilon TDf(p_0)]\), and \(DQ_e(p_0) = DQ_0(p_0) + O(\varepsilon^2)\). Additionally, as shown in step (e), the fundamental averaging result Thm. 1(i) shows that \(Q_e(p_0) = p_0 + O(\varepsilon)\).

Now incorporating the reset,
\[
DP_e(p_0) = DR(Q_e(p_0)) \cdot DQ_e(p_0)
\]
\[
= DR(p_0 + O(\varepsilon)) \cdot DQ_e(p_0)
\]
\[
= (S_0 + \varepsilon S_1(p_0 + O(\varepsilon))) \cdot DQ_e(p_0)
\]
\[
\leq (S_0 + \varepsilon S_1(p_0) + O(\varepsilon^2)) \cdot DQ_e(p_0)
\]
\[
= (S_0 + \varepsilon S_1(p_0)) \cdot DQ_0(p_0) + O(\varepsilon^2)
\]
\[
= DR(p_0) DQ_0(p_0) + O(\varepsilon^2)
\]
\[
= DP_0(p_0) + O(\varepsilon^2).
\]
where for the step *, we used the fact that \(S_1\) is Lipschitz continuous.

By the hypotheses in the statement of Thm. 2(ii), we know that \(P_0\) has a fixed point at \(p_0\), but we need to show that \(P_e\) has a fixed point that is close. From the block equation above, \(DP_e(p_0) = S_0 + \varepsilon (S_1 + TDf(p_0)) + O(\varepsilon^2)\). By passing to the Jordan form, without loss of generality we assert that \(S_0 = V \begin{bmatrix} I_{m/e} & 0 \\ 0 & I_{n-m} \end{bmatrix} V^{-1}\) (using the hypothesis that “1” eigenvalues have algebraic multiplicity 1 from Thm. 2(ii)), where \(U\) does not have a unity eigenvalue. Now let \(E(\varepsilon) := V \begin{bmatrix} I_{m/e} & 0 \\ 0 & I_{n-m} \end{bmatrix} V^{-1}\). Define
\[
\zeta(p, \varepsilon) = E(\varepsilon)(P_e(p) - p).
\]
Note that \(\zeta(p, 0) = 0\), and letting \(\bar{S}_1 := S_1 + TDf(p_0)\)
\[
V^{-1} DP_e(\zeta(p_0, \varepsilon) V
\]
\[
= V^{-1} E(DP_e - I) V
\]
\[
= \left[ I_{m/e} \ 0 \\ 0 \ 0 \right] \left[ \begin{bmatrix} I_{m/e} & 0 \\ 0 & I_{n-m} \end{bmatrix} V^{-1} DP_e V - I \right]
\]
\[
= \left[ I_{m/e} \ 0 \\ 0 \ 0 \right] \left[ \begin{bmatrix} I_{m/e} & 0 \\ 0 & I_{n-m} \end{bmatrix} V^{-1} \bar{S}_1 V - I \right]
\]
\[
= \left[ I_{m/e} \ 0 \\ 0 \ 0 \right] \left[ \begin{bmatrix} 0 & 0 \\ 0 & U^{-1} I_{n-m} \end{bmatrix} + \varepsilon V^{-1} \bar{S}_1 V \right].
\]
In the limit \(\varepsilon \to 0\), the top \(m\) rows have rank \(m\), since \(\bar{S}_1\) is full rank (hyperbolicity of the return map \(DP_0(p_0)\) asserted in the hypotheses). The bottom \(n - m\) rows evaluate to \(U - I - n_{-m}\); since \(U\) has no unity eigenvalues, \(U - I_{n-m}\) is also full rank. For \(\varepsilon > 0\), the argument is unchanged for the first \(m\) rows. For the bottom rows, the entries of \(U - I_{n-m}\) dominate those of \(\varepsilon V^{-1} \bar{S}_1 V\) for sufficiently small \(\varepsilon\), and so by continuity of eigenvalue with matrix entries, the right hand is full rank. Thus, \(DP_e(\zeta)\) is full rank, and using implicit function theorem, we know there is a family of fixed points \(p_0\) for \(P_e\), and \(p = p_0 + O(\varepsilon)\).

As shown in step (e) in the proof of Thm. 1(ii), we have \(DQ_e(p_0) = DQ_0(p_0) + O(\varepsilon^2)\), and we showed in the steps leading to (17) that \(DR(Q_e(p_0)) = DR(p_0) + O(\varepsilon^2)\). Similar to those steps, we can show that \(DR(Q_e(p_0)) = DR(p_0) + O(\varepsilon^2)\) Putting these together,
\[
DP_e(p_0) = DR(Q_e(p_0)) DQ_e(p_0)
\]
\[
= (DR(p_0) + O(\varepsilon^2))(DQ_0(p_0) + O(\varepsilon^2))
\]
\[
= DP_0(p_0) + O(\varepsilon^2).
\]
Following step (f) in the proof of Thm. 1(ii), we conclude the desired result.

### 2.3 Hybrid systems (event-based reset)

Hybrid systems arising in legged locomotion and other fields often encounter a discrete reset at a state-dependent “event,” unlike the fixed flow time we assumed in the previous section. The event is usually described as the intersection of the continuous flow with a guard surface, \(\mathcal{G}\), which triggers a discrete reset of the system state. The time
Figure 1. We define a class of hybrid averageable systems (Thm. 3) with a single domain, fast (ς) and slow (x) coordinates, with general conditions on the flow (dark orange), and requirements on fixed points of the flow and the reset. The calculations in Thm. 3 show how to construct a new hybrid system with constant flow time (yellow, guard $\mathcal{G} := (T \times \mathcal{X})$ for any hybrid system with variable flow time (purple, guard $\mathcal{G} = y^{-1}(0)$) by augmenting with a flow-to-reset map.

 elapsed between these events generally varies with initial condition.

In this section we show that the variable event time can be incorporated in a modified reset, effectively reducing this more general case to the switching case, enabling application and generalization of Thm. 2.

Theorem 3. Hybrid Averaging Theorem. Given the "original" hybrid system

\[
\begin{align*}
\dot{x} &= \varepsilon f(x, \sigma, \varepsilon), \quad \dot{\sigma} = 1, \\
y(x, \sigma) &= 0 \implies x_+ = R(x, \sigma)
\end{align*}
\]  

and "averaged" switching system

\[
\begin{align*}
\dot{y} &= \varepsilon \hat{f}(y), \quad \dot{\sigma} = 1, \\
\sigma = T \implies y_+ = \hat{R}(y),
\end{align*}
\]  

where $\hat{R}$ is constructed from $R$ as defined in the proof (23), we assert the following hypotheses on (19)–(20). If

(i) assuming $D_\sigma \gamma = 1,^7$ the guard set satisfies $D_x \gamma = O(\varepsilon),$

(ii) the $C^r$ (for $r \geq 2$) reset $R$ (allowed to vary with $\varepsilon$) satisfies (a) $D_x R(x, \sigma) = S_0 + \varepsilon S_1(x, \sigma, \varepsilon)$ (with constant $S_0$), (b) $S_0$ is invertible, and its unity eigenvalues have diagonal Jordan blocks, and

(iii) there is a point $p_0$ and $T > 0$, such that (a) $p_0$ is an equilibrium of $\hat{T}$, (b) $R(p_0, T) = p_0$, $\varepsilon y(p_0, T) = 0$, and (d) the matrix $S_0 = \varepsilon (U + V)$, where $\varepsilon U := \varepsilon S_1(x, T, \varepsilon) - D_\sigma R \cdot D_x \gamma, \ v := TD\hat{f}$ is hyperbolic at $p_0, T$.

then there exists $\varepsilon_0 > 0$ such that, for all $0 < \varepsilon \leq \varepsilon_0$, (19) possesses a unique hyperbolic periodic orbit, of the same stability type as $p_0$.

Proof. We first provide a construction that enables us to locally transform a system with variable flow time (19), to a system with constant flow time that has equivalent $^8$ Poincaré (i.e., flow-and-reset) dynamics. Let $\Phi(x, \sigma)$ denote the maximal flow associated with the continuous dynamics of (19) from initial condition $(x, \sigma = T).$ $^9$ Since $\dot{\sigma} \equiv 1, \pi_\sigma \Phi(x, \sigma) = T + \sigma$. Any initial condition $(x, 0)$ impacts the guard as

\[
y \circ \Phi(x, \sigma) = 0.
\]  

where $\sigma$ may be negative. Define the time-to-event $\hat{\tau} := \int_0^\tau \frac{\frac{1}{\varepsilon D_x \gamma} \cdot \hat{f} + 1}{\varepsilon D_x \gamma \cdot \hat{f} + 1} D\hat{y} = \frac{\varepsilon D_x \gamma}{\varepsilon D_x \gamma \cdot \hat{f} + 1}, \tag{22}
\]

since we assumed $D_\sigma \gamma = 1$ without loss of generality. Define the time-$T$-flow equivalent reset $\hat{R} := \pi_\sigma U \rightarrow \mathcal{X}$ by

\[
\hat{R}(x) := R \circ \Phi(x, \tau(x)). \tag{23}
\]

Differentiating with respect to $x$ using chain rule, and substituting using (22) we compute

\[
D_x \hat{R}(x) = DR \cdot (D_x \Phi(x, 0) + D_\sigma \Phi \cdot D\tau)
\]

\[
\equiv DR \cdot \left( \begin{bmatrix} T \ v \end{bmatrix} - \frac{1}{\varepsilon D_x \gamma \cdot \hat{f} + 1} \left[ \begin{bmatrix} 0 \\
1 \end{bmatrix} \right] D_x \gamma \right)
\]

\[
= D_x R - D_\sigma R \cdot D_x \gamma + O(\varepsilon^2), \tag{24}
\]

using the hypothesis that $D_x \gamma = O(\varepsilon)$, and where $\sigma$ is evaluated at $T$ on the right hand side.

Let $\Phi_\varepsilon$ now denote the flow of the continuous dynamics of (19) starting from initial condition $(x, \sigma = 0)$. Consider the switching system

\[
\dot{x} = \varepsilon f(x, \sigma, \varepsilon), \quad \dot{\sigma} = 1, \quad \sigma = T \implies x \mapsto \hat{R}(x), \tag{25}
\]

and its flow-and-reset return map

\[
\hat{R} \circ \Phi_\varepsilon(x, T) \equiv R \circ \Phi_\varepsilon(\Phi_\varepsilon(x, T), \tau \circ \Phi_\varepsilon(x, T)),
\]

which corresponds exactly to the return map for (19).

Additionally, note that $D_x \hat{R} = S_0 + \varepsilon U$, and that the
averaged return map for (20) would be
\[
\begin{align*}
D\bar{P}(p_0) &= D\bar{R}(p_0)(f + \varepsilon TD\bar{f}) + O(\varepsilon^2) \\
&=: S_0 + \varepsilon(U + V) + O(\varepsilon^2). 
\end{align*}
\] (26)

With the hyperbolicity of \(D\bar{P}(p_0)\), all of the conditions of Thm. 2 are satisfied by the systems (25) and (20), and upon its application, we get the desired result.

**Remark 2.** Relation to smoothing. Hybrid systems of the form (19) satisfying the conditions of Thm. 3 (henceforth referred to as “averageable” hybrid systems in this paper) are **smoothable** in the sense that they satisfy the hypotheses of (Burden et al. 2015, Thm. 3). Since that result gives a conjugacy to a classical (non-hybrid) vector field and since the smoothing does not affect the \(\varepsilon\)-dependence of the vector field, it is unsurprising that we are able to extend classical averaging theory to the present hybrid setting. The contribution in this paper is the provision of a constructive—in fact, computational (e.g., Sec. 4.1)—method useful for stability analysis of hybrid systems.

**Remark 3.** Lower and upper bounds on \(\varepsilon\). The conclusion of the preceding Lemma is formally valid only for \(\varepsilon > 0\) sufficiently small. However, it may be possible in practice to obtain lower or upper bounds on the allowable range for \(\varepsilon\):

a) Since we have invoked IFT in the proof of Thm. 1, it is straightforward (if tedious) to bound the size of the neighborhood in which (2) has a periodic orbit as in (Abraham et al. 1988, Supplement 2.5A). Alternatively, singular perturbation methods Tsatsos (2006) may provide lower bounds on values of \(\varepsilon\) that ensure the conclusions of Thm. 1 hold.

b) An obstruction to enlarging the upper bound on \(\varepsilon\) appears in our example in Sec. 4.1: the quotient (41) is only valid when \(\tilde{x}_1 > 0\), which is violated when \(\varepsilon > \omega\).

### 2.4 Symmetry-factored hybrid averaging

Thm. 3 applies to systems with a single continuous flow (“mode” in hybrid systems terminology Burden et al. (2015)) punctuated by discrete reset events, as modeled in (19). We are able to use this result to demonstrate stability of a “monoped” in the upcoming Sec. 4.1. We develop two small extensions to the theoretical result in the following two subsections that allow the result to be applicable in a broader class of “biped” systems that we detail below.

The sagittal plane vertical hopper model we present in Sec. 3 can have four physical modes (resulting from none, one of the two, or both legs in stance), and Fig. 2 suggests how the focus only on in-phase or anti-phase limit cycles leads to a formal reduction to the “single mode with reset” hybrid system (Thm. 3). For the in-phase case (bottom row of Fig. 2) the limit cycle of interest passes through only two modes (double support and flight). In Sec. 2.5, we will observe that our control affordance (each leg of the abstract “machine” analyzed here—and indeed the physical machine to be analyzed in the companion paper De and Koditschek (2016)—has two independently actuated degrees of freedom) allows us to force operation into this regime where integrating the aerial dynamics reduces the flight mode to a mere factor of a single mode reset map (as we show in the single-leg example of Sec. 4.1). However, for the anti-phase case (top row of Fig. 2), the limit cycle of interest passes through three modes and even after replacing the flight flow with its integrated reset map, we must still extend the Thm. 2 result to a class of hybrid systems with two continuous modes. We achieve this extension by imposing a symmetry condition on the dynamics of the two alternating single stance modes in order to specialize the notion of a standard hybrid dynamical system as defined in (Burden et al. 2015, Def. 1), as follows.

**Corollary 1.** Given a tuple \(\tilde{H} = (\bar{X}, \bar{F}, \bar{\gamma}, \bar{\Gamma}, K)\) such that

(i) \((\bar{X}, \bar{F}, \bar{\gamma}, \bar{\Gamma}, K)\) is a hybrid dynamical system as defined in (Burden et al. 2015, Def. 1) with two modes in the same domain \(\bar{X}\), i.e. index set \(J = \{1, 2\} \approx \mathbb{Z}_2\) (we use \(\approx\) to make explicit that these elements are disjoint unions of domains or maps as per convention);

(ii) \(K : \bar{X} \to \bar{X}\) is an involutive symmetry, i.e. \(K^2 = \text{id}\);

(iii) the vector field, guard, and reset respect the symmetry, i.e. (a) \(\bar{D}K \cdot \bar{F}_{(j+1)} \circ K = \bar{F}_j\), (b) \(\gamma_{(j+1)} \circ K = \gamma_j\), and (c) \(\bar{R}_{(j+1)} \circ K = K \circ \bar{R}_j\circ K\),

a limit cycle of the kind depicted in Fig. 2B has a return map that can be factored as

\[
\bar{P} = (P_{(0)})^2, \text{ where } P_{(0)} := K \circ R_{(0)} \circ Q_{(0)}. 
\] (27)

**Proof.** The first condition in (iii) essentially states that \(F_{(j)}\) are conjugate through the \(K\); from this we automatically conclude that

\[
K \circ Q_{(j+1)} = Q_{(j)} \circ K, 
\] (28)

where \(Q_{(j)}\) is the flow of \(F_{(j)}\) till it intersects the guard surface \(\gamma_{(j)}\). For a limit cycle of the kind depicted in Fig. 2B, the full return map can be factored:

\[
\begin{align*}
\bar{P} &= R_{(1)} \circ Q_{(1)} \circ R_{(0)} \circ Q_{(0)} \\
&= (K \circ R_{(0)} \circ K) \circ Q_{(1)} \circ R_{(0)} \circ Q_{(0)} \\
&= (K \circ R_{(0)} \circ (Q_{(0)} \circ K) \circ R_{(0)} \circ Q_{(0)} \\
&= (P_{(0)})^2. 
\end{align*}
\]
Figure 2. A depiction of the two kinds of hybrid dynamical limit cycles analyzed in this paper. In the full (visualized as two-dimensional) product domain, there are four possible modes corresponding to each of the two legs being in flight or stance. We (locally) analyze two limit cycles (A); one with alternating stances interspersed with aerial phases (blue), and one with “short” single stance periods. In the former case, we use symmetry (Sec. 2.4) to factor the return map into two iterations of a “half return map” (27) (B, C), integrate the trivial aerial dynamics, and get a single-mode hybrid system (D). In the latter case, we assume that active toe extension control (Sec. 2.5) can be used to eliminate the short single-stance periods and enforce simultaneous transition between aerial and double stance modes (E, F), integrate the trivial aerial dynamics, and recover another single-mode hybrid system (G). In Sec. 4.2 and the “weakly coupled hoppers” section in De and Koditschek (2016) we analyze a limit cycle of form D, and in Sec. 4.3, and the “strongly coupled hoppers” De and Koditschek (2016) we analyze a limit cycle of form G.

$P_{(0)}$ in (27) is a “half return map.” It is clear from Corollary 1 that the stability properties of the limit cycle are fully described by the half return map. Consider the single-mode hybrid system, $H_{(1)} = (\mathcal{X}_{(1)}, F_{(1)}, \mathcal{S}_{(1)}, K \circ R_{(1)})$. The return map of $H_{(1)}$ is simply $P_{(1)}$ for all limit cycles of the kind shown in Fig. 2B.

Thus, the symmetry properties in Corollary 1(iii) allow us to analyze the single-mode system $H_{(1)}$ and make conclusions about limiting behavior of $\overline{H}$. Accordingly, suppressing the single-mode subscript label, we return to the specialized structure of systems compatible with Thm. 3 and consider the tuple $H = (\mathcal{X}, F, \mathcal{S}, R, y^*)$, where $\mathcal{X} := \mathcal{X}_{(1)}$, $F := F_{(1)}$, $\mathcal{S} := \mathcal{S}_{(1)}$, $R := K \circ R_{(1)}$ (again, we emphasize that we have dropped the subscripts since we need only analyze behavior in the first mode), and $y^*$. In the analytical results of Sec. 4, we apply Thm. 2 or Thm. 3 for our stability analyses in Secs. 4.2 and the “weakly coupled hoppers” section of De and Koditschek (2016).

Remark 4. Note that we have made the following notational changes from (Burden et al. 2015, Def. 1): (a) we prefer an implicit (though non-unique) description of the guard set, i.e. $\gamma_{(j)}$ is any function such that $\mathcal{S}_{(j)}(\gamma_{(j)})^{-1}(0)$; (b) we use parenthesized subscripts for the index set; and (c) we make use of a (non-unique) implicit representation of the guard, $\gamma_{(j)}(\mathcal{S}_{(j)}) \equiv 0$. Apart from notation, it is important to note that the domain for each continuous mode is the same space, $\mathcal{X}$, and not separate disjoint domains as in Burden et al. (2015).

Remark 5. Symmetry-factoring has been previously exploited to simplify return map calculations in Altendorfer et al. (2004). In that case, time-reversal symmetry of Hamiltonian SLIP within a single stance is utilized to factor the SLIP return map, whereas in this paper, we utilize the symmetric steps of a bipedal gait as in Schmitt and Holmes (2000) in order to factor the full return map that represents a complete stride into a “half-return map” (27) that only contains a single step. More generally, notwithstanding the present-seeming special nature of these factorizations, we suspect that symmetry analysis of this nature will play an important role in many more legged locomotion settings.

2.5 Near-simultaneous transitions

We now consider the in-phase limit cycle depicted in the bottom row of Fig. 2. Specifically, as anticipated above, we bring its analysis under the sway of the restricted single mode framework of Thms. 2–3 by enforcing transitions through the higher codimension guard set intersections where both toe-touching constraints are active.

Assumption 1. In the limit cycles of type Fig. 2E–G, active control of the leg extension is used in the aerial phase to execute simultaneous touchdown and liftoff.

Since the actuators only have to move the toes (small inertia), this action can, in principle, be made almost devoid of any energy cost.

We provide numerical and empirical justification for this assumption following the introduction of more physically realistic models in the companion paper De and Koditschek (2016). In the “near-simultaneous transitions” section of De and Koditschek (2016), we compare traces from
simulations with active toe extension control in aerial phase either enabled or disabled from a variety of initial conditions to illustrate how the resulting trajectories become nearly indistinguishable after a few strides. Independently, even without imposing such active control on the physical Minitaur robot, the relative frequency of single stance in empirical preflexing is low—6.31% when preflexively preflexing in-place (with modified body inertia), and 6.65% when preflexing with feedback-stabilized body pitch, as shown in plots in De and Koditschek (2016)—lending support to our “simultaneous transition” assumption for the preflexing analysis (Sec. 2.5). It is worth noting in passing that these empirical observations, revealing as they do the rarity (even absent active control) of single stance in preflexing, lend further support to the suggestion emerging from the analysis of Burden et al. (2016) (motivated by the prevalence of virtual bipedal and monopedal gaits in biology) that such high codimension transitions might, themselves, be preflexively attracting.

3 Model task: vertical hopping

The application domain that motivated the preceding theoretical developments is legged locomotion on land. A well-known model for running is that of a mass suspended on a massless leg by a (physical or virtual) spring Geyer et al. (2006); Blickhan and Full (1993). We begin here by considering one (29) or multiple (depicted in Fig. 3) vertically-constrained legs: a useful model for investigating in-place hopping, bounding (two legs hopping out of phase), and preflexing (two legs hopping in phase).

Apart from the utilitarian interest of this regime (where, as we will show in Sec. 4, it is straightforward to command both in-phase preflexing and anti-phase bounding) the effectively decoupled dynamics greatly simplifies the analysis, easing the introduction of notation and and permitting simpler stability proofs (that are, nevertheless, strongly evocative of the subsequent preflex stabilized regimes to be analyzed in the companion paper, De and Koditschek (2016)).

3.1 Equations of motion

Consider a physical plant with a pair of vertically-constrained masses (of unit mass), suspended by massless legs with nominal extension \( \rho \in \mathbb{R}_+ \). The configuration variables of interest are physical heights of the masses, \( z_i \in \mathbb{R}_+ \).

We get two modes, stance and flight, based on whether the height is less than the nominal leg extension (as formalized below in (29)). The equations of motion for the two hoppers (indexed by \( i \in I := \{1, 2\} \)) are

\[
\begin{align*}
\ddot{z}_i &= \left\{ \begin{array}{ll}
-g + \Upsilon_i & z_i < \rho, \text{and} \\
-g & \text{else,}
\end{array} \right. \\
\end{align*}
\]

(29)

where \( \Upsilon_i \) is the shank extension force generated by leg \( i \). We discuss scaling the controller parameters in relation to the morphological parameters more in De and Koditschek (2016), but for this paper we assume that the shank extension controller compensates for the known dynamical parameters as

\[
\Upsilon_i := g + u_i,
\]

(30)

where \( u_i \) is the parameter-agnostic “template controller” signal which we define below in (31).

3.2 Model space description

In this section we introduce our preferred coordinates for analysis, and show the results of transforming the vertical-hopper-pair’s decoupled equations of motion (29). We also introduce the template controllers used in this paper for, first, height regulation in single legged vertical hopping and, then, coordination control in two-legged vertical hopping.

3.2.1 Vertical hopper control We set the template vertical hopper controller in stance to have a physical Blickhan and Full (1993) or virtual Kenneally et al. (2016) spring-like force, together with a nonlinearity \( v_i(\vec{s}) \) (comprising damping as well as active inputs, see (37)) which affects asymptotic stability:

\[
\begin{align*}
u_i := \omega^2 (\rho - z_i) + \varepsilon v_i(\vec{s}),
\end{align*}
\]

(31)

where \( \vec{s} = (z_1, z_2, \dot{z}_1, \dot{z}_2) \) is the full state vector of the system in Fig. 3. Note that there is no gravity compensation term in the template controller above; in (30) just above we declared the relation between (31) and its use as the physical control input in the various plant models in this paper (such as \( \Upsilon_i \) in (29)).
3.2.2 Energy-phase coordinates We write the physical vertical (position and velocity) coordinates in their phase canonical form, \( p : \mathbb{R}^2 \rightarrow \mathbb{R}^2 \),

\[
p(z_i, \dot{z}_i) := \left[ \begin{array}{c} -\dot{z}_i \\ (\rho - z_i) \omega \end{array} \right],
\]

(32)

where \( \omega > 0 \) is the stance frequency, and consider the square-root-of-energy coordinate \( a_i \in \mathbb{R}_+ \),

\[
a_i := \left\{ \begin{array}{ll} \| p(z_i, \dot{z}_i) \| & z_i < \rho, \\
\sqrt{2g(z_i - \rho) + \dot{z}_i^2} & \text{else.} \end{array} \right.
\]

(33)

Note that \( m_ha_i^2/2 \) (in Joules) represents the total mechanical energy of a vertical hopper. However, motivated by the analytical simplicity of the resulting stance dynamics (Sec. 4.1, 4.2), we find it convenient to assume unit mass and work in the square root. Consequently, the units of \( a_i \) in (33) reduce to square root of (mass specific) energy at touchdown, \( a_i \) is continuously defined around the cycle. As the reader might anticipate, this quantity derived from the total mechanical energy has slow dynamics in a desirable periodic orbit of a hopper, and indeed, we show this in \( (41) \). This makes \( a_i \) a good candidate to be one of the “x” coordinates of Thm. 3, and indeed we use it in such capacity in Sec. 4.1.

Also define the corresponding phase, \( \psi_i \in \Psi \subset \mathbb{R} \),

\[
\psi_i := \left\{ \begin{array}{ll} \angle p(z_i, \dot{z}_i) & z_i < \rho, \\
\frac{\dot{z}_i}{2a_i} & \text{else,} \end{array} \right.
\]

(34)

where “\( \angle \theta \)” refers to the “angle of \( \theta \in S^1 \)” and the stance phase is the natural completion of the polar coordinate transformation in (33), the flight phase definition is from Klavins et al. (2000), and we refer the reader to Remark 6 again for the implications of the discontinuity in this definition.

Note that around the cycle, \( \psi_i \) goes from 0 to \( \pi \) in stance, and from 0 to 1 in flight. Define the “flight frequency,”

\[
\omega_f : \mathbb{R}_+ \rightarrow \mathbb{R}_+ : a_i \mapsto g/(2a_i).
\]

(35)

The abstract phase definition here is inspired by the work of Klavins et al. (2000). However, the process of generating a constant-slope phase coordinate (referred to as a “smoothing” step in (Klavins et al. 2000, Sec. 3.2)) is much more difficult in our case because of the various nonlinearities and coupling forces. We discuss further connections to Klavins et al. (2000) in A.1.

Remark 6. Continuity in maps from physical to model coordinates. All dynamical models considered in this paper fall within the class of self-manipulation hybrid systems Johnson et al. (2016) and are thus guaranteed to have unique and non-blocking executions. We further show, using the distinct strategies depicted in Fig. 2, that they satisfy the requirements of Thm. 3, placing them within the class of “smoothable” hybrid systems (Burden et al. 2015, Thm. 3)—so that their executions are guaranteed as well to vary continuously with respect to initial conditions, and be piecewise smooth. Because our coordinate transformations, e.g., (34) are written for convenience across the distinct modes of the original physical coordinates of the self-manipulation system, they are not formally continuous functions. However, as depicted in Fig. 2, both routes to the single mode averageable model set out in Thm. 3 subsume into its formal reset map the erstwhile continuous flows through “uninteresting” (and integrable) modes of the physical coordinates, so that (34) and (36) operate only in a single mode in which they are indeed smooth functions.

3.2.3 Phase differences For the analyses we present in Sec. 4 and the analysis section in De and Koditschek (2016), the principal tool we use is single-mode hybrid averaging (Thm. 2–3). The result allows us to make local stability conclusions about hyperbolic hybrid limit cycles, but is only applicable to continuous dynamics with a single “fast” variable (which can be thought of as a phase-like coordinate). In order to express the dynamics of our plant models in terms amenable to application of hybrid averaging, we use our intuition to find appropriate slow “phase difference” coordinates (36). This idea is inspired by Proctor et al. (2010), where differences of phases of identical coupled oscillators are shown to be slow, and a classical averaging application follows.

We introduce the following local (by this we mean that \( \delta \) is a smooth function of the physical states while in a single hybrid mode, but discontinuous across modes\(^{11} \)) definition for “phase difference”:

\[
\delta := \tau_1 - \tau_2, \text{ where }
\]

\[
\tau_i := \left\{ \begin{array}{ll} (\psi_i - \pi/2)/\omega & z_i < \rho, \\
(\psi_i - 1/2)/\omega(a_i) & \text{else.} \end{array} \right.
\]

(36)

Note that the coordinates above have the units of time (this is apparent from the definition above, since \( \psi_i \) are unitless in (34), and \( \omega (31) \) and \( \omega_f (35) \) both have units of \( s^{-1} \).)

3.2.4 Oscillatory energization and phase control The \( v_t \) term in our vertical hopper control (31) contains the various nonlinearities responsible for asymptotic stability and phase control. This includes a lumped viscous friction term (which is assumed to come from unavoidable parasitic sources), as well as terms introduced by feedback:

\[
v_t(\hat{s}) := -\beta \dot{z}_i - K_a \cos \psi_i + w_i(\hat{s}),
\]

(37)

where the second summand in the last equation is an oscillatory energization term De and Koditschek (2015b).
that can intuitively be thought of as “negative damping”\textsuperscript{12}, and the last summand introduces a new feedback phase-control term. The phase controller expressed in the functional form of $w_i(x)$ is discussed in Sec. 3.3.

3.3 Coordination controllers

In this paper we propose two kinds of coordination controllers. First, we introduce a phase controller\textsuperscript{13} with phase control gain $k_d \in \mathbb{R}$,

$$w_i(\vec{x}) = (-1)^{i-1}k_d(\dot{z}_1 - \dot{z}_2)\sin \psi_i.$$  

(38)

Looking ahead, setting $k_d > 0$ in Sec. 4.2 stabilizes an anti-phase limit cycle (the template for a “bounding” gait in the “weakly coupled hoppers” section in De and Koditschek (2016)), whereas setting $k_d < 0$ in Sec. 4.3 stabilizes a limit cycle entraining the two legs in-phase (the template for a “pronking” gait in the “strongly coupled hoppers” section in De and Koditschek (2016)).

Second, we introduce an empirically-motivated attitude controller (only for pronk stabilization) which adds a proportional control term to (38),

$$w_i(\vec{x}) = (-1)^{i-1}(k_p(z_1 - z_2) + k_d(\dot{z}_1 - \dot{z}_2)).$$  

(39)

for $i \in \mathbb{I}$.

We verify analytically the efficacy of these controllers with respect to the mechanically isolated hoppers of Fig. 3 in Sec. 4. In the companion paper we will show, first, that these stability results persist for a weakly mechanically coupled instance of the hoppers De and Koditschek (2016) and then, turn to a similar but more intricate analysis of what we will term “preflexive” stabilization wherein the influence of two distinct modes of (first, stronger, and then much stronger) mechanical coupling substitutes in place of any feedback control.\textsuperscript{14}

We remark here that (38) and (39) are both trivial to implement on a physical platform, since the only sensory information required is of the coordinate $z_1 = z_2$, and its derivative. For example, on the physical Minitaur robot of the companion paper De and Koditschek (2016) this information can be measured directly through the physical angle $\phi$ and its derivative.

4 Analytical results

Our stability analyses of the various models and control schemes take the form of systematically working through the checklist of conditions of Thm. 2 or 3.

The generalization to variable flow-time achieved by Thm. 3 (over Thm. 2) allows us to account for variable stance duration caused by the nonlinear forcing (31), (37) the springy leg is subject to. In Sec. 4.1, we model in detail the weakly varying (45) stance duration and account for this effect in the linearized return map Jacobian (26). However, just as (Raibert 1986, Ch. 2) argues, we find in our empirical tests referenced from the table of assumptions in De and Koditschek (2016) that the variation in stance duration of a spring-mass system with weak forcing is negligible. Thus, we enforce a constant stance time assumption (Assumption 2) for Sec. 4.2-4.3 to simplify our exposition. Nonetheless, we include the requisite calculations for a variable-flow-time-version of the Sec. 4.2 analysis in Sec. 4.2.4 in order to convey to the reader the conceptual simplicity of the computations. We anticipate that Thm. 3 will have great utility in situations where the flow duration varies significantly, such as the “preloaded” leg spring strategies explored in (Raibert et al. 1989, eq. (4.6)) for high-speed running.

4.1 Single vertical hopper

To demonstrate the applicability of hybrid averaging to analysis of physical systems, we first investigate a 1DOF hybrid system. We consider one of the two hoppers depicted in Fig. 3: a unit mass restricted to travel along its vertical axis with an attached massless leg. We choose this as our first example for two reasons. First, despite its apparent simplicity, it serves as a template for ubiquitous running and hopping behavior in robots and animals Blickhan and Full (1993). Variants of this model have been analyzed extensively in the literature, e.g. see Koditschek and Buehler (1991) for an analysis of this one degree-of-freedom (1DOF) restriction of a planar point-mass model whose energizing input is inspired by the empirically successful strategies reported in Raibert (1986). Second, the simplicity of the equations of motion mitigate the intricacies of the hybrid averaging, exposing in particular the synergistic relationship of this method with symmetry, which we discuss further in Sec. 4.1.1.

Informed by the structure of the averaging results of Sec. 2, we propose an alternative energization scheme (intuitively similar but physically distinct from Raibert (1986)) and apply Thm. 1 to establish an analogous stability result. The analyses in Koditschek and Buehler (1991) relied on two simplified models that both admitted closed form return maps (Koditschek and Buehler 1991, eqns. (15), (17)). However, hybrid averaging allows a stability analysis without requiring integrable\textsuperscript{15} stance dynamics (e.g. (41)). Recall that even the “simple” 2DOF SLIP dynamics Saranli et al. (1998) are non-integrable, hence motivating an analysis tool that drops this requirement.

4.1.1 Continuous dynamics For the following analysis, we choose (in the language of Thm. 3) the coordinates $\sigma := x_1(x)$, and $x := a_1 \in \mathbb{R}$.

Using the previously declared vertical hopper model in (3.1) and control in (31) and (37); setting $w_i \equiv 0$ (because...
there is no “other” hopper to coordinate for now) in the system dynamics (29), (30), we derive the stance \((a_1, \psi_1)\) equations of motion of the hopper, below.

Define \(q := \rho(z_1, \dot{z}_1)\) from (32). The physical equation of motion in stance (from (29) and (31)) is
\[
\ddot{z}_1 = \omega^2 (\rho - z_1) + \epsilon v_1,
\]
and rewritten in terms of \(q\) are
\[
\dot{q}_1 = -\ddot{z}_1 = \omega^2 (z_1 - \rho) - \epsilon v_1 = -\omega q_2 - \epsilon v_1, \\
\dot{q}_2 = -\ddot{z}_1 = q_1 \omega.
\] (40)

Using (33), \(a_1 = \|q\|\), and from the equations above,
\[
a_1 \dot{a}_1 = q_1^T \dot{q} = -\epsilon v_1 \dot{q}_1 = -\epsilon v_1 (a_1 \cos \psi_1) \\
\Rightarrow \dot{a}_1 = -\epsilon v_1 \cos \psi_1.
\]

where we used the polar coordinate transformation of \(q\), i.e., \(q_1 = a_1 \cos \psi_1\), and \(q_2 = a_1 \sin \psi_1\). For the \(\psi_1\) dynamics, note that
\[
\dot{\psi}_1 \overset{(40)}{=} \frac{1}{a_1^2} (q_1^2 \omega^2 - q_2 (-\omega q_2 - \epsilon v_1)) \\
= \frac{1}{a_1} (\omega^2 (q_2^2 + q_2^2) + \epsilon v_1 q_2) = \omega + \epsilon v_1 \sin \psi_1 / a_1
\]
since \(q_1^2 + q_2^2 = a_1^2\).

We observe that for sufficiently small \(\epsilon > 0\), we have \(\dot{\psi}_1 > 0\), allowing us to divide \(\dot{a}_1\) by \(\dot{\psi}_1\). Now in the language of Thm. 3, \(\sigma = \psi_1, x = a_1\), and we can write
\[
\frac{\partial \dot{a}_1}{\partial \psi_1} = \frac{-\epsilon \cos \psi_1 v_1}{\omega + \frac{\epsilon}{a_1} \sin \psi_1 v_1},
\]
(41)

where \(v_1\) is as given in (37). Note that the system takes the form of (19). Consider the prospective fixed point for the averaged system,
\[
T = \pi, \quad y^* = k_\sigma / \beta,
\] (42)

where the value of \(T\) corresponds to the state having traversed the entire half plane of stance (i.e., the state of liftoff) and the value of \(y^*\) (i.e., energy \(a_1^2\)) corresponds to the equilibrium energy suggested by the second summand of (37). Using this \(T\) for direct integration of the stance vector field (41) from touchdown through to liftoff, we get (now, as in (2), letting \(y = a_1\)),
\[
\overline{f}(y) := \int_0^\pi f(y, \sigma, 0) d\sigma = -\int_0^\pi v_1 \cos \psi_1 d\psi_1 \\
= \frac{(k_\sigma - a_1 \beta)}{2 \omega},
\]
(43)

which indeed evaluates to 0 at \(y^*\) (42), satisfying Thm. 3(iii).

In intuitive terms, we point out that the oscillatory control signal introduced in (37) has the special property that the \(k_\sigma\)-term is odd in \(\psi_1\) in the first row of (41), whereas it is even in \(\psi_1\) in the second row. Consequently, after the averaging step, \(k_\sigma\) persists in the averaged \(a_1\)-dynamics (43). In more complex future analysis expanding on these ideas (as discussed in the conclusion), we see that similar odd symmetries (e.g. last row of (53)) are helpful in eliminating coupling interactions.

4.1.2 Guard set The guard set is defined by the physical liftoff event when the normal force at the toe-ground interface during stance goes to 0, and from (29) and (30), we see that this happens when \(u_t = 0\) in (31):
\[
y(x, \sigma) := \tan \psi_1 - \frac{\epsilon (k_\sigma / a_1 - \beta)}{\omega},
\]
scaled such that \(D_\sigma y = 1\) at \(\sigma = T\). Also, \(D_\sigma y = 0\) at \(\sigma = 0\), satisfying Thm. 3(i). Lastly, note that \(y(y^*, T) = 0\) at the fixed point of the averaged vector field (43), satisfying Thm. 3(iii). Additionally, we can calculate
\[
Dy(y^*, T) = \begin{bmatrix} 1 & 0 \end{bmatrix} \frac{\epsilon \beta^2}{k_\sigma \omega^2}.
\] (45)

We observe that Lemma 1 allows us to apply both \(x\) and \(y\)-coordinates as arguments to \(y\), since both sets of coordinates coincide at liftoff time.

4.1.3 Reset map As in De and Koditschek (2015a), the massless in-flight leg is reset to its nominal length, \(\rho\). It follows from (34) that the touchdown phase, \(\psi_1\) is identically zero since \(z_1 = \rho\) at the touchdown event. Noting from (34) that \(\ddot{z}_1 = -a_1\) at touchdown, and recalling that the mechanical energy \(a_1\) is conserved in flight (33), we can solve for \(a_1\) at touchdown, yielding
\[
R(x, \sigma) = \sqrt{a_1^2 \cos^2 \psi_1 - 2 a_1 \sin \psi_1 / \omega}
\] (46)
\[
\Rightarrow DR(y^*, T) = [1, g/\omega].
\] (47)

where \(S_0 := 1\) is constant, satisfying Thm. 3(ii). Also, \(R(y^*, T) = y^*\) from (46), satisfying Thm. 3(iii). Again, we observe that Lemma 1 allows us to apply both \(x\) and \(y\)-coordinates as arguments to \(R\).

4.1.4 Stability test We can calculate \(U\) according to the definition in Thm. 3 to get
\[
S_0 + \epsilon U = D_\sigma R - D_\sigma RD_\gamma y \overset{(45),(47)}{=} 1 - \frac{\epsilon \beta^2}{k_\sigma \omega^2},
\]
where the second summand was introduced by the variable flow time. As pointed out in the introduction of Sec. 4.1, this effect empirically appears to be negligible, likely due to

Prepared using sagejcls
the small magnitude of the second summand. We can also compute $V$ by differentiating (43) to get $V = -\frac{\pi \beta}{2x}$.

As in (26), using the previous computations, the averaged return map linearization is

$$
D\bar{P}(y^*) = 1 - \varepsilon \left( \frac{g\beta^2}{k_a \alpha \tau^2} + \frac{\pi \beta}{2\omega} \right),
$$

which is stable as well as hyperbolic for small $\varepsilon > 0$. We conclude from Thm. 3 that the (unaveraged) vertical hopper also has a stable fixed point that is $\varepsilon$-close to (42). We present numerical demonstration of this result in Sec. 5.1.

### 4.2 Two vertical hoppers: anti-phase limit cycle (bounding template)

Here we present a local analysis of the anti-phase limit cycle with alternating stances of hoppers 1 and 2, the results of which are borne out in empirical trials in De and Koditschek (2016).

We appeal to Corollary 1 with symmetry (48), and study the half return map with the continuous dynamics $F := F_{(1)}$—where mode “1” we now define as the one where hopper 1 is in stance, hopper 2 in flight—and where the reset $R := K \circ R_{(1)}$, where $R_{(1)}$ maps states from liftoff of hopper 1 to touchdown of hopper as depicted in the upper series of sketches in Fig. 2.

The full state space thus has four dimensions. The symmetry map (Corollary 1(iii))

$$
K : \mathbb{R}^4 \to \mathbb{R}^4 : (a_{(j)}, \psi_{(j)}) \mapsto (a_{(j+1)}, \psi_{(j+1)}),
$$

is helpful in defining the reset maps in Sec. 4.2 and the “weakly coupled hoppers” section of De and Koditschek (2016).

For this subsection and the next, we enforce the following assumption, whose justification is referenced from the assumptions table in De and Koditschek (2016).

**Assumption 2.** The stance duration (resulting from a weakly perturbed spring-mass oscillation) is constant.

As described in the introduction of Sec. 4, our empirical trials display more-or-less constant flow time, and we find that the further complication in algebra does not buy any new insight. Still, we include a variable-flow-time version of the return map computation (and stability analysis) that appears in Sec. 4.2.3 to demonstrate in a tutorial manner how an application of Thm. 3 would proceed.

#### 4.2.1 Continuous dynamics

For the following analysis, we choose the coordinates $\sigma := \psi_1$, and $x := (a_1, a_2, \delta)$, where $\delta$ is the phase difference coordinate introduced in Sec. 3.2.3. The projection of the symmetry map $K$ to these $x$-coordinates is a linear map defined by the matrix

$$
\bar{K} := \begin{bmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix} \in \mathbb{R}^{3 \times 3}.
$$

The continuous dynamics (29) can be rewritten in the coordinates defined in (33)–(34), as we have already shown for the stance leg in Sec. 4.1, (41).

For the leg in flight ($\dot{a}_2, \dot{\psi}_2$), from the second row of (33),

$$
\frac{d}{dt} a_2^2 = a_2 \dot{a}_2 = g \ddot{z}_2 + \ddot{z}_2 \ddot{z}_2 = \ddot{z}_2 (\ddot{z}_2 + g) \equiv 0,
$$

and from the second row of (34),

$$
\dot{\psi}_2 = \frac{g}{2a_2} \ddot{z}_2 \equiv \frac{g}{2a_2} \equiv \omega_2(a_2).
$$

Putting it all together,

$$
\dot{a}_1 = -\varepsilon \cos \psi_1 v_1, \quad \dot{a}_2 = 0, \\
\dot{\psi}_1 = \omega \equiv \frac{\psi_1 v_1}{a_1}, \quad \dot{\psi}_2 = \omega_2(a_2),
$$

where the $\varepsilon$ parameter appears in these positions due to our choice of $\varepsilon$–magnitude nonlinearity in the hopper control (31) so as to depend upon the anti-phase stabilizing version ($k_d > 0$) of the phase coordination term $\omega_1$ defined in (38).

Using the phase difference coordinate $\delta$ from (36) (note that hopper 1 is in stance and hopper 2 is in flight for the analysis in this subsection), we notice that

$$
\frac{d}{dt} \delta = \frac{\varepsilon}{a_1} \sin \psi_1 v_1, \quad \dot{\delta} = \frac{\sin \psi_1 v_1}{a_1},
$$

i.e. by inspection, the presence of the “small” parameter, the factor $\varepsilon$ in (52), reveals that the chosen phase difference coordinate is “slow” ($O(\varepsilon)$ dynamics). The continuous dynamics in these coordinates are

$$
\dot{\delta} = \omega + \frac{\sin \psi_1 v_1}{a_1}, \\
\dot{\chi} = \varepsilon \begin{bmatrix} -\cos \psi_1 v_1 \\ 0 \\ \sin \psi_1 v_1 / a_1 \end{bmatrix}.
$$

Consider the prospective anti-phase fixed point,

$$
T = \pi, \quad y^* = \begin{bmatrix} k_a / \beta, \ k_a / \beta, \ 0 \end{bmatrix}^T, \quad (54)
$$

where

$$
\bar{k}_a := k_a, \quad \bar{\beta} := \beta - \frac{4k_d}{3\pi}.
$$

Though the last entry of (54) is zero, we emphasize that this denotes an “anti-phase” limit cycle: observe in (36) that
when hopper 2 attains apex, \( r_1 = 1/2 \), then \( \delta = 0 \) implies that, simultaneously, the hopper must be experiencing its “bottom” (most compressed) event.

Additionally, note from (54) that the the \( k_d \) gain introduced through our phase controller (38) moves the first two components, of the equilibrium, \( y^* \), which evaluates to 0 at

\[
ap = 0,
\]

when hopper 2 attains apex,

\[
\delta = 0,
\]

which row of (34) is used in each appearance of \( \psi \). Note that the \( a_i \) are defined continuously through modes (33), and the \( \alpha_i \) are unchanged by ballistic flight.

Define \( t_{LO} \) as the liftoff time (when hopper 1 is in stance, hopper 2 is in flight) and \( t_{TD} \) as the touchdown time (when hopper 1 is in flight, hopper 2 is in stance). In this reset calculation, to avoid confusion, we will be explicit about which row of (34) is used in each appearance of \( \psi_i \); e.g.,

\[
\psi_i = (a_2 - \dot{z}_2)/(2a_2).
\]

First, we integrate the Jacobian as

\[
\Delta \bar{J}(y) = \begin{bmatrix}
-\frac{\bar{g}}{2\chi} & 0 & 0 \\
0 & \frac{\bar{g}k_d}{2\omega^2a_1} & 0 \\
\frac{-\bar{g}k_d}{2\omega^2a_1} & 0 & -\frac{\bar{g}k_d}{2\omega^2a_1}
\end{bmatrix}.
\]

We use this in (34) to calculate

\[
\psi_i = \psi_i(t_{LO}) = \psi_i(t_{TD}) + \omega_1 a_1(t_1) t_1 = \frac{1 - \psi_i(t_{LO})}{\omega_1 a_2(t_1)}.
\]

Now we must express the above in terms of \( \delta \). Using the appropriate patches at \( t_{LO} \) and \( t_{TD} \),

\[
\delta(t_{LO}) = \frac{\psi_i(t_{LO}) - \pi/2}{\omega_1} - \frac{\psi_i(t_{LO}) - 1/2}{\omega_1 a_2(t_1)}
\]

\[
\delta(t_{TD}) = \frac{\psi_i(t_{TD}) - 1/2}{\omega_1 a_1(t_1)} - \frac{\psi_i(t_{TD}) - \pi/2}{\omega_1}.
\]

Per our constant flow-time assumption (Assumption 2), we know that \( \psi_i(t_{LO}) = \pi \), and combining with (59),

\[
\delta(t_{LO}) = \frac{\pi}{2\omega} - \frac{\psi_i(t_{TD}) - 1/2}{\omega_1 a_2(t_1)}.
\]

Since the leg touches down at its nominal extension, by (34), \( \psi_i(t_{TD}) = 0 \), and combining with (59),

\[
\delta(t_{TD}) = \frac{\psi_i(t_{TD}) - 1/2}{\omega_1 a_1(t_1)} = \frac{\delta(t_{LO}) + \psi_i(t_{TD}) - 1/2}{\omega_1 a_2(t_1)}.
\]

Substituting (58) into the above,

\[
\delta(t_{TD}) = \delta(t_{LO}) - \frac{1}{\omega_1 a_2(t_1)} - \frac{1}{\omega_1 a_1(t_1)} + \frac{1}{\omega_1 a_2(t_1)} + \frac{1}{\omega_1 a_1(t_1)} = \delta + \frac{(a_2-a_1)}{g}.
\]

All together, the slow-coordinate reset is

\[
R(a_1, a_2, \delta) = \psi_1 \circ K \circ \begin{bmatrix}
1 & 0 \\
a_2 & a_1 \\
\delta + \frac{(a_2-a_1)}{g}
\end{bmatrix} = K \begin{bmatrix}
a_1, & a_2, & \delta + \frac{(a_2-a_1)}{g}
\end{bmatrix}^T.
\]

From the above, we observe that \( DR : \Omega \to \Omega \) has a constant \( \Omega(1) \) part, satisfying Thm. 2(i).

1.5.4.3 Application of switching averaging Using (49), (57), and (62) and evaluating at (54), we get the averaged return map

\[
\Delta \bar{F} = \begin{bmatrix}
0 & 1 & 0 \\
0 & 0 & 1 \\
\frac{\delta_1}{g} & -1 & -1 + \frac{\bar{\gamma}k_d}{2\omega^2a_1}
\end{bmatrix},
\]

where

\[
\delta_1 := \frac{1 - \bar{g}}{2\omega},
\]

only depends on constant parameters. The block lower triangular \( \Delta \bar{F} \) has eigenvalues \( \pm j \sqrt{\delta_1} \) from the upper left block (the upper block has complex conjugates hence the determinant is their magnitude squared), and \(-1 + \frac{\bar{\gamma}k_d}{2\omega^2a_1}\) from the scalar lower right block, which is within the unit circle for small \( \varepsilon > 0 \).
that $\bar{b} > 0$. Assuming our gains are set appropriately, for small $\varepsilon > 0$, $|\xi_1| < 1$, and also the other eigenvalues are within the unit circle since their product is $\xi_1$, and the averaged return map is stable. Additionally, the return map is hyperbolic, and applying Thm. 2, we conclude that the pair of independent hoppers has a stable anti-phase limit cycle $\varepsilon$–close to (54).

4.2.4 Variable flow-time (event-based reset) analysis

This section contains a “tutorial” description of how Thm. 3 can be applied (without requiring Assumption 2) to the bounding analysis of Sec. 4.2. We point out specific departures from the constant-flow-time version of the analysis below, and end by juxtaposing the return map linearization (66) against its constant-flow-time counterpart (63).

Guard set First, the guard set is defined by the “normal reaction crossing zero” event as in (44).

Reset Next, the reset map is modified in two of its entries:

a) Note that $a_1$ is constant through flight, but we need to convert its stance coordinates at the time of liftoff (depending on when the guard surface (44) is intersected) to flight coordinates. Thus, the $a_1$–reset is replaced instead by (46) (see (65) below).

b) Additionally, the phase difference reset calculation is modified. We replace (60) with the guard (44), and get

$$\delta(t_{LO}) = \frac{\tan^{-1}(\varepsilon k_a/(\omega a_1) - \beta)}{2\omega} - \frac{\psi(2)(t_{LO}) - 1/2}{\omega(a_2)}$$

Using this together with (61), we get

$$\delta(t_{TD}) = \delta(t_{LO}) + \frac{1}{2\omega(a_2)} - \frac{1}{2\omega(a_1)} + \frac{\pi - \tan^{-1}(\varepsilon k_a/(\omega a_1) - \beta)}{2\omega}$$

Putting these together, and applying the symmetry operation (48)

$$R^{(1)}(x, \psi_1) = \begin{bmatrix} \sqrt{a_1^2 \cos^2 \psi_1 - 2g a_1 \sin \psi_1 / \omega} \\ a_2 \\ \delta + \frac{(a_2 - a_1)}{\varepsilon} + \frac{\pi - \tan^{-1}(\varepsilon k_a/(\omega a_1) - \beta)}{2\omega} \end{bmatrix}$$

Note from (54) that

$$R\left(\begin{bmatrix} \frac{k_a}{\varepsilon} & 0 \\ k_a & \beta \end{bmatrix} \right) = \begin{bmatrix} k_a & 0 \\ k_a & \beta \end{bmatrix}$$

satisfying $\overline{R}(y^*) = y^*$ in Thm. 3(iii). Next, we use (24) to find $D\overline{R}$. Using the guard (44) and the reset (65), and evaluating at the fixed point (54), we get

$$D\overline{R}(1)(y^*) = \begin{bmatrix} 1 - \frac{\varepsilon g \beta^2}{k_a \omega} & 0 & 0 \\ 0 & 1 & 0 \\ -1/g & 1/g & 1 \end{bmatrix}$$

which has a constant $O(1)$ part. We also note the similarity between the top left entry and Sec. 4.1. Repeating the steps in Sec. 4.2.3, we obtain the averaged return map

$$D\overline{P} = \begin{bmatrix} 0 & 1 & 0 \\ \frac{\xi_1 - \varepsilon g \beta^2}{k_a \omega} & 0 & 0 \\ \frac{\xi_1}{g} & -1/g & 1 + \frac{\varepsilon g k_a \beta}{2 k_a \omega^3} \end{bmatrix}$$

Note that the eigenstructure of this matrix is similar to its constant-flow-time counterpart (63). In fact, since $\xi_1 - \varepsilon g \beta^2 < \xi < 1$ for small $\varepsilon$, the eigenvalues for the block lower triangular matrix above are within the unit circle.

4.3 Two vertical hoppers: in-phase limit cycle (pronking template)

In this section we show that phase control (38) (albeit now with $k_d < 0$) can be applied to the same independent hoppers model as in the previous subsection (Fig. 3) but now used to stabilize a different limit cycle.

As depicted in the lower succession of sketches in Fig. 2, we think of this limit cycle as having a single continuous mode (double stance) followed by a reset (aerial phase), assuming simultaneous transitions as discussed in Sec. 2.5. With this assumption in force, we now show, in counterpoint to the previous section (where the introduction of a symmetry operator (48) achieves a re-factorization of the three physical modes depicted in Fig. 2B into the “half-stride” paired modes depicted in Fig. 2C), how these different hybrid dynamics can directly be modeled as executions of a single-mode averageable hybrid system.

In this instance, we again use the switching theorem (Thm. 2) and ignore the small variation in the flow duration.

4.3.1 Continuous dynamics As in (51), but this time, since both legs are in stance, for $i \in \mathcal{I}$ we get (29) for both legs. Use the phase difference $\delta$ in the double stance patch from (36), and notice that

$$\frac{d}{dt}\delta = \frac{\varepsilon}{\omega^2} \left( \frac{v_2 \sin(\omega \delta - \psi_1)}{a_2} + \frac{v_1 \sin \psi_1}{a_1} \right) =: f_\delta(x),$$

i.e. the phase difference is “slow” analogously to its counterpart (52) in the anti-phase limit cycle analysis of the preceding Sec. 4.2.1. Once again as in Sec. 4.2, we use the
coordinates, $\sigma = \psi_1 + \pi/2$ and $\chi := (a_1, a_2, \delta)$, and see that
\begin{equation}
\begin{aligned}
\dot{\sigma} &= \omega + \frac{\varepsilon}{a_1} \sin \psi_1 v_1 \\
\dot{\chi} &= \varepsilon \begin{bmatrix}
-\cos \psi_1 v_1 \\
-\cos(\omega \delta - \psi_1) v_2
\end{bmatrix}.
\end{aligned}
\tag{68}
\end{equation}
where $f_\beta(x)$ is defined above in (67). Recall we are using the same phase controller (38) as in Sec. 4.2, but now with $k_d < 0$. Introducing the prospective in-phase fixed point,
\begin{equation}
T = \pi, \quad y^* = [k_a/\beta, k_a/\beta, 0]^T,
\end{equation}
we point out here that the equilibrium phase difference above is very different from the one in (54) despite the visual similarity, due to the different definition of $\delta$ (which is, as before in Sec. 4.2, local). For recall, once again, that in Sec. 4.2.1 we considered hopper 1 to be in stance and hopper 2 to be in flight, whereas now both hoppers are assumed to be in stance. Consequently, (36) shows that $\delta$ is zero iff both hoppers attain “bottom” simultaneously.

Equation (37) is now substituted into (68), thereby selecting a $k_d$ for a desired $y^*$ through (69), and (68) is integrated (we used the Integrate function in Mathematica 10.2 to perform this integral),
\begin{equation}
\bar{f}(y) = \begin{bmatrix}
(k_d - a_1 \beta) - 2k_d (a_1 - a_2c) \\
(k_d - a_2 \beta) - 2k_d (a_1 c - 2a_2c) \\
-2 k_d (2a_2^2 + a_1 a_2 \delta^2 + 2a_1^2 c) \\
3 \pi \omega a_1 \delta \\
3 \pi \omega a_2 \delta \\
\end{bmatrix},
\end{equation}
where $s := \sin(\omega \delta)$, and $c := \cos(\omega \delta)$. Despite the complexity, we observe the following about the averaged vector field (70):

\begin{enumerate}
\item[a)] the prefixive $k_d = 0$ case recovers the isolated vertical hopper $a_1$-dynamics (29) for both hips (first summand in each of the first two rows);
\item[b)] when $\delta = 0$, and $a_1 = a_2$, we also recover isolated vertical hopper dynamics in the first two rows, suggesting that behavior close to the equilibrium resembles that of independent vertical hoppers;
\item[c)] in A.1 we provide an interpretation of the last row as a proportional controller on the phase difference, $\delta$.
\end{enumerate}

The averaged vector field (70) evaluates to 0 at $y^*$, satisfying Thm. 2(ii). Moreover, we can calculate the Jacobian and evaluate at $y^*$ to get
\begin{equation}
D\bar{f}(y^*) = \begin{bmatrix}
-\zeta_2 - \zeta_3 & \zeta_3 \\
\zeta_3 & -\zeta_2 - \zeta_3 \\
0 & 0
\end{bmatrix}.
\end{equation}
where we define the new constants $\zeta_2 := \frac{\beta}{2 \omega}$, and $\zeta_3 := \frac{8 k_d}{3 \pi \omega}.$

### 4.3.2 Reset

The touchdown condition is the touchdown of hopper 1 after its flight phase, or when $\psi_1 - 1$ (34) crosses zero. As in Sec. 4.2.2, $a_1$ are not modified by the aerial dynamics. To integrate the aerial dynamics, note first that since the touchdown event is at the zero of $1 - \psi_1^{(1)}(t)$, and $\psi_1^{(1)}(t_{TD}) = 0$, the time of flight is simply $t_f = 1/\omega(a_1)$. In this time, hopper 2 must finish its stance phase, complete its flight phase, and proceed through its stance phase (where some of these times may be negative):
\begin{equation}
t = \frac{\pi - \psi_2^{(2)}(t_{TD})}{\omega} + \frac{1}{\omega(a_2)} + \frac{\psi_2^{(2)}(t_{TD})}{\omega}.
\end{equation}

To express in terms of $\delta$, note that
\begin{equation}
\delta(t_{TD}) = \frac{\pi - \psi_2^{(2)}(t_{TD})}{\omega}, \delta(t_{TD}) = -\frac{\psi_2^{(2)}(t_{TD})}{\omega}.
\end{equation}

Using the above in (72), we get
\begin{equation}
\frac{1}{\omega(a_1)} = \delta(t_{TD}) + \frac{1}{\omega(a_2)}.
\end{equation}

Rearranging, using (35), and putting together with the energy coordinates, we get
\begin{equation}
\bar{R}(a_1, a_2, \delta) = \begin{bmatrix}
1 - 2 (a_2 - a_1)  \\
\zeta_3 \\
\zeta_3 \\
0 \\
0 \\
\end{bmatrix}.
\end{equation}

Just as in Sec. 4.2.2, $y^*$ in (69) when substituted into the equation above yields $\bar{R}(y^*) = y^*$, satisfying Thm. 2(ii), and also we note that $\bar{D}\bar{R}$ has a constant 0(1) part, satisfying Thm. 2(i).

Note that unlike the reset map for the anti-phase limit cycle (62), $\bar{R}$ does not appear here, since we only have a single-mode hybrid system in consideration for the in-phase limit cycle.

### 4.3.3 Application of switching averaging

Using (71), and (73) and evaluating at (69), we get the averaged return map
\begin{equation}
\bar{D}\bar{F} := \bar{D}\bar{R} \cdot (I + \varepsilon \pi \bar{D}\bar{f}_1)
\end{equation}
\begin{equation}
= \begin{bmatrix}
1 - 2 \varepsilon(\zeta_2 + \zeta_3) & 0 & 0 & \varepsilon \zeta_3 & 0 \\
\varepsilon \zeta_3 & 1 - 2 \varepsilon(\zeta_2 + \zeta_3) & 0 & 0 & \varepsilon \zeta_3 \\
-2(1 - \varepsilon(\zeta_2 + \zeta_3)) & -2(1 - \varepsilon(\zeta_2 + \zeta_3)) & 1 - \varepsilon(\zeta_2 + \zeta_3) & 0 & 0 \\
\end{bmatrix}.
\end{equation}

where $\zeta_i$ are as defined in Sec. 4.3.1. This lower triangular matrix has $1 - \frac{\varepsilon k_d}{3 \pi a}$ as one of its eigenvalues, which is within the unit circle for small $\varepsilon > 0$. The symmetric upper left block has the simple eigenvalues $\{1 - \varepsilon \zeta_2, 1 - \varepsilon \zeta_2 - 2 \varepsilon \zeta_3\}$, which are also within the unit circle for small $\varepsilon > 0$.

Moreover, $\bar{D}\bar{F}$ is hyperbolic, and using Thm. 3, we conclude that the pair of independent hoppers has a stable in-phase limit cycle $\varepsilon$-close to (69).
5 Numerical results

In this section we present simulation results of the model systems discussed in this paper. In Sec. 5.1 we display overlapping traces of “unaveraged” and “averaged” dynamics on an isolated vertical hopper, showing the correspondence that is formally established by Thm. 1. In Sec. 5.2, we demonstrate the efficacy of the new coordination controllers introduced in Sec. 3.3 on a pair of informationally-coupled, mechanically-decoupled vertical hoppers.

We would like to remind the reader that the companion paper De and Koditschek (2016) contains a much larger swath of not just numerical but also empirical results benefitting from the theoretical contributions of this paper.

5.1 1DOF vertical hopper

Using parameters $\omega = 50$ rad/s, $k = 0.4$ N-s/m$^2$, $\beta = 10$ N/(m/s) and $\epsilon = 2$, numerical simulations of the vertical hopper with Mathematica 10, using NDSolve and WhenEvent show that

a) the fixed point of the averaged system is approximately 0.15 mm away from the original system’s fixed point (Fig. 4 middle, difference between purple $a$ and dashed gray $a^*$), and

b) the residual error between trajectories of the averaged and original systems are an order of magnitude smaller than $a^* = k/\beta = 0.04$ m (Fig. 4, bottom).

Remark 7. approximating continuous control with discrete steps. Note that the averaged vector field (43) has the form of a proportional controller on total energy. Thus

Thm. 1 enables us to conclude that the cumulative control effect on body height from multiple isolated steps through a second-order ODE is approximately equivalent to that of a first-order ODE acting on body height (as shown in Fig. 4(middle)): the gold traces in the middle plot correspond to the averaged system, and “snipping away” the resets recovers a smooth energy dynamics corresponding to (43).

5.2 Pair of vertical hoppers

In Fig. 5 we illustrate numerically the analytical results just derived in Sec. 4.2–4.3. The physical model we use is the pair of vertical hoppers of Fig. 3, and we demonstrate that our new phase controller (38) can stabilize both anti-phase...
and in-phase limit cycles by changing the sign of the scalar parameter $k_d$.

We provide empirical demonstration of the phase controller on a physical platform as well as empirical application of the attitude controller (39) in the companion paper De and Koditschek (2016) in the “feedback synchronization” empirical results section.

We also show in A.1 how the phase controller (38) behaves in closed loop like an abstract phase control such as previously analyzed in Klavins et al. (2000). The empirical benefit of (38) is that it is a smooth function of data $\phi, \dot{\phi}$ measured from sensors on the robot, whereas the abstract phase difference (36) is not only an involved calculation, but also a discontinuous function of the physical state.

6 Conclusion

This paper presents, to the best of our knowledge, the first instance of a generalization to hybrid systems of a classical averaging result. Thus, Thm. 1 joins a growing body of cases wherein suitably constructed hybrid systems Burden et al. (2016, 2015); Elderling and Jacobs (2016); Ames and Sastry (2006); Westervelt et al. (2003); Posa et al. (2016) admit an appropriately restated version of classical dynamical systems results, with useful applications to new engineering settings.

6.1 Relaxing and extending the required conditions

We provide some examples that demonstrate limitations of the present theory, and in doing so, motivate future theoretical work.

6.1.1 Extension to multiple domains Intuitively, the $\varepsilon$-parameterization of the continuous dynamics in (1) ensures that all non-phase coordinates vary slowly with respect to the phase. Robotic systems in steady-state operation—with asymptotically stable limit cycles—are one (important) class of systems our results apply to, but by no means the only.

An additional limitation in our modeling is the single continuous mode and reset of (19). Generalizing the results herein to hybrid systems with multiple modes or overlapping guards presents a number of challenges. With multiple domains, there is no privileged set of coordinates shared across disjoint portions of state space, so it is not obvious how to parameterize the flow to the form of (1). With overlapping guards, the return map is generally discontinuous (Remy et al. 2010, Table 3) or at least nonsmooth (Burden et al. 2016, Sec. 4.2), so it is not obvious how to generalize conditions on the guard and reset in Thm. 3.

6.1.2 Effects of $\varepsilon$-perturbation As discussed in Remark 3, large-$\varepsilon$ limits of classical averaging conclusions can be found in the literature (e.g. (Tsatsos 2006, pg. 17)). Numerically, as well as from our empirical experience in De and Koditschek (2015a), the vertical hopper example in Sec. 4.1 retains the asymptotic behavior of (43) for large $\varepsilon$ (Sec. 5.1).

6.1.3 Rank condition in Thm. 2(ii), Thm. 3(iii) We emphasize that this condition is necessary for averaging along the lines of hyperbolicity in the classical theory (Guckenheimer and Holmes 1990, Thm. 4.1.1). Indeed, consider the switching system with flow-time $T$, dynamics

$$\dot{x} = -\varepsilon x, \quad R(x, \sigma) = x + \varepsilon T x,$$

and observe that $\overline{f} = -x$ and $D\overline{f} = -1$. Note that the linearization of the return map,

$$D\overline{R} \cdot D\overline{Q}(x) = (1 + \varepsilon T)(1 - \varepsilon T) + O(\varepsilon^2) = 1 + O(\varepsilon^2),$$

is not hyperbolic to $O(\varepsilon)$, so we cannot assess stability using Thm. 2.

6.2 Applications and extensions in higher dimensions

Application to a simple 1DOF model relevant to legged locomotion (Sec. 4.1) indicates that stability analyses of limit cycles in higher dimensional systems Kenneally et al. (2016); De and Koditschek (2015b) could be greatly simplified, in analogy to the simple construction afforded by De and Koditschek (2015a) relative to the initial controllers of De and Koditschek (2015b). This is an avenue of ongoing research being undertaken by the authors, and would add to the large body of emerging engineering-motivated research to develop approximations of the behavior of nonlinear dynamical systems near reference trajectories Wu and Sreenath (2015); Manchester (2011); Ames et al. (2014); Rijnen et al. (2016) (limit cycles in the case of this paper).

In current and future work, we wish to apply this method to systems of much higher dimensionality than considered here or in the companion paper De and Koditschek (2016). We believe that the following insights will be key in generalizing this method:

- **Time-reversal symmetry.** As we observe in the last paragraph of Sec. 4.1.1, the averaging method bears a particular synergy with phase-symmetry. The prevalence of symmetry in locomotion Raibert (1986); Altendorfer et al. (2004); Razavi et al. (2016) motivates and encourages further application of the methods introduced here. Work currently in
progress reveals that time-reversal symmetry can help find averageable coordinates for a class of hybrid dynamical systems appearing in legged locomotion (such as the examples here), easing the work of representing the continuous dynamics in the form of Thm. 2.

- **Conservation laws.** High-dimensional systems often exhibit symmetries leading to conservation laws, as seen for instance in SLIP or LLS (lateral leg spring) Holmes et al. (2006). Conservation laws can be leveraged for dimension reduction before application of our hybrid averaging ideas in this paper, especially since conserved quantities contribute to non-hyperbolicity in the return map, thereby precluding application of Thm. 2.

- **Dimension reduction using feedback anchoring.** The traditional view of anchoring Full and Koditschek (1999), or (hybrid) zero dynamics Westervelt et al. (2003), is that of dimension reduction in the form of an attracting invariant submanifold of the original system. We foresee that our averaging ideas could be applied to the restricted dynamics (“template dynamics” or “zero dynamics”), i.e. after an initial reduction (anchoring) due to passive mechanics or stabilizing feedback control.

**Acknowledgements**

The authors would like to acknowledge Dr. John Guckenheimer for a personal communication that greatly aided our interpretation of Thm. 1, and suggested our new Lemma 1.

**Funding**

This work was supported in part by NSF grant #1028237, in part by the U. S. Army Research Laboratory and the U. S. Army Research Office under contract/grant number W911NF-16-1-0158 awarded to the second author, and in part by ONR grant #N00014-16-1-2817, a Vannevar Bush Fellowship held by the last author, sponsored by the Basic Research Office of the Assistant Secretary of Defense for Research and Engineering.

**Notes**

1. Note that we evaluate at $\varepsilon = 0$ since these terms interact with a Taylor expansion at $\varepsilon = 0$ of $\dot{y}$, as shown in (6).
2. Typo in Guckenheimer and Holmes (1990); should have said $D\overline{f}(p_0)$ instead of $Df(p)$.
3. This statement means that if $p_0$ is a hyperbolic fixed point of $\overline{f}$, by definition, the eigenvalues of $D\overline{f}(p_0)$ have a non-zero real part. Consequently, the eigenvalues of $\exp(\varepsilon TD\overline{f}(p_0))$ do not lie on the unit circle.
4. Typo in Guckenheimer and Holmes (1990); not $x^2$-close.
5. Intuitively, the result of (i) holds over a time interval of $O(1/\varepsilon^2)$. This statement says that since $T$ doesn’t depend on $\varepsilon$, for small enough $\varepsilon$, the $O(1/\varepsilon)$ time interval over which (i) applies can be $> T$.
6. The $1/\varepsilon$ in $\xi$ is there to maintain invertibility even as $\varepsilon \to 0$, since $\lim_{\varepsilon \to 0} D\Phi_\varepsilon \to I$.
7. This can be done without loss of generality by scaling $\gamma$ as long as $D\gamma \neq 0$, which we assert as a condition on the transversality of the flow and the guard.
8. We use the term “equivalent” to denote a correspondence stronger than conjugacy; whereas the flows are indeed conjugate, the return maps are identical.
9. This initial condition corresponds to the nominal impact time, not the initialization of the continuous dynamics at $\sigma = 0$. Additionally, the reader should note that we keep “$x$” arbitrary for now, i.e. the following calculations hold for any $x$.
10. We envision that exploiting within-stance time-reversal symmetry as in Altendorfer et al. (2004) could augment the method in this paper, for further analytical benefit (as we pursue with work already in progress seeking to analyze the composition of this paper’s in-place behaviors with the fore-aft motions treated as disturbances in the “empirical compositions” section in De and Koditschek (2016)).
11. The discontinuity of (36) across modes does not introduce any analytical issues as discussed in Remark 6.
12. From (34), $-k_{d\omega} \cos \psi_1 = (e k_d / a_i) I_2$ (forcing in the direction of velocity, but normalized by $a_i$).
13. Though the arguments of (38) seemingly involve only physical coordinates, we justify the use of the term phase controller by exposing the strong relation between the energetically relevant “proportional / dissipative” form of (38)–(39), and abstract phase control in Sec. A.1.
14. Additionally, in the companion paper De and Koditschek (2016), we numerically and empirically test these controllers on systems with preflexive stabilization as well (though we omit these analyses of combined preflexive–feedback stabilization for sake of space and clarity).
15. We remind the readers of the distinction between an integrable flow, and the averaging integral (2). In the latter case, we integrate the vector field over a single “phase” parameter while holding the other states constant.
16. A function $f$ such that $f(x) = f(-x)$ is odd in $x$, and one such that $f(-x) = f(x)$ is even in $x$.
17. Practitioners may wish to note that $x$-closeness in state corresponds to $x$-closeness in energy in mechanical systems like this hopper.

A Appendix

This appendix contains various calculations that are used for our stability proofs, broken down by the section in which they appear.

A.1 A physical surrogate for abstract phase difference (Sec. 3.3)

In each of Sec. 4.2–4.3, a more straightforward proof involving algebraically simpler terms could have been obtained by introducing instead of (38) a coordination term based upon the abstract phase difference

$$w_i(x) = (-1)^{i-1} k_i \sin \psi_i \sin (\omega t) ,$$

as in (Klavins et al. 2000, eqn. (7)). This is because in both of the preceding averaging analyses, $\delta$ is shown to be a “slow” coordinate ($\dot{\delta} = O(\epsilon)$), and can be held constant while performing the averaging integral in (56) and (70).

However, the analytically simpler alternative (75) requires computation of the abstract phase difference $\delta$ for implementation, which is quite involved (36), especially due to the discontinuities in its definition across modes. In comparison, our globally well-defined phase controller (38) is a simple function of the physical variables that can be easily measured with sensors. We observe in Sec. A.1.1 that, notwithstanding its simplicity, the coordination controller (38) actually functions as a physical surrogate for the abstract phase difference, behaving, in both the in-phase and anti-phase cases, like a proportional phase controller in the averaged sense. We then discuss the numerical and empirical utility of this simply implemented surrogate in Sec. A.1.2.

Although a matter of considerable conceptual interest, we are not aware of an analogously equivalent “abstract” version of the attitude controller (39) that is a function of the $\psi_i$ coordinates only.

A.1.1 Closed-loop phase-difference dynamics

Though our phase controller (38) looks quite different from the abstract version (75),

1) an inspection of the last row of (56) reveals that $\dot{\delta} \approx -\delta$, and

2) inspection of the $\sin(\omega t)$ factor in (or application of the Series function in Mathematica to) the last row of (70) reveals that $\dot{\delta} \approx -\delta(a_1^2 + a_2^2) + O(\delta^2)$,

where we use the $\approx$ symbol and omit constant positive parameters, but include all functions of state explicitly. In both cases, the closed-loop $\delta$ dynamics take the form of a proportional control on $\delta$ for small $\delta$, which is identical to the (75).

A.1.2 Numerical comparison

Fig. 5 shows a numerical comparison between the abstract phase control (75) and the approximation (38) for both positive and negative signs of the gain $k_d$, respectively stabilizing a bounding and a pronking limit cycle in a pair of independent hoppers.

In the companion paper De and Koditschek (2016), we show in simulation our approximated phase control applied to coupled vertical hoppers, and more importantly, on the physical platform. Our results show that (38) is able to overcome preflexive stability and stabilize the physical platform leg phases to a desired limit cycle for trotting and pacing, as well as to obtain bounding or pronking.
